was no less than £3,720,745. In 1895, the value of the produce only amounted to £1,652,275; while the value of machinery and plant and sites stood at £711,051, and wages paid at £180,775. That is to say, while the value of the capital employed rose by 25 per cent., the amount paid in wages rose by 20 per cent., and the value of the produce by 125 per cent. Butter and cheese factories rank second in importance under this heading, giving occupation to 1,188 hands at 247 factories, who received in wages £96,433. The total value of invested land, buildings, and machinery stood at £388,750. The value of the output is estimated at £1,535,150. Here, again, there have been tremendous advances during five years, the output being threefold, while the number employed has doubled, and the capital has increased by 60 per cent. Under this heading are several minor industries, such as fish, bacon, and ham curing, rabbit packing, and making of condensed milk.

Passing over the preparation of vegetable food, drinks, narcotics and stimulants, we come to industries involving a greater amount of manual and mechanical labour, such as wood working occupations.

Saw-mills, Sash and Door Factories. — These number 334 and employ 6,812 hands, who receive in wages £513,888. The cost of manufacture is a dominant feature with regard to output in work of this character. It is, therefore, not surprising to find that the value of the manufactured produce amounts to £1,268,689, or roughly 2½ times the wages paid, as against 20 times the value of the wages paid in the meat freezing and preserving works. The capital invested in these factories amounts to £703,620. Mechanical power is largely employed, no less than 8,744 horse-power being installed. As compared with the state of affairs in 1895 the number of hands employed have increased by 70 per cent., the value of the manufactured output by 33 per cent., and the capital by 20 per cent.

Paper-making is in an elementary stage, only three mills being in operation, employing 98 hands. Save that an aggregate of 705 horse-power is installed, other particulars such as total wages paid, value of output, etc., are suppressed in order that individual works may not be identified.

Gas and Electricity Supply Works.—Gasworks are erected at 30 places, employing 572 hands. The wages paid amount to £70,573, and the value of the output to £290,567. In numbers these works have only increased by three in five years; during this period six electric lighting works have been established, employing a small staff of 52 hands. The value of land, buildings, plant and machinery used for gasworks amounts to £971,559, and for electrical works to £64,156.

Iron and Brass Foundries, Boiler-making Machinists, &c., are doubtless well occupied in helping to meet the requirements of other industries. There are 35 factories in this class, employing 1,955 hands. The wages paid amount to £162,647. The value of plant, buildings, and machinery stood at £211,282, and the value of the manufactured produce stood at £508,906.

Engineering Works are separately defined for the first time in 1900. The distinction between a machinist's or a boiler-maker's and an engineer's work is one which cannot be readily drawn at this distance. In these 1,442 hands receive as remuneration £127,635. The value of finished articles produced amounts to £361,958. In the 1895 return this and the previously mentioned industry are lumped together, and it is therefore difficult to reckon the advance with the clearness desirable. The combined output has increased nearly three-fold, and the combined number of *employés* has doubled.

Agricultural Implements.—The making of these goods, an industry largely of an engineering nature, employs 586 hands, who earned in 1900 £53,941. These turned out goods to a total value (including repairs) of £138,094. Among the articles manufactured locally were 869 ploughs, 864 harrows, 242 rollers, 75 windmills, 89 wool presses, and numerous other goods.

Textile Industries.—These are at present very much in their infancy. There are 10 woollen mills—industries inevitably tend towards the source of one or other of their raw materials—employing a total of 1,693 hands, of whom 769 are male and 924 are female. The wages paid amount to £112,001, while the value of the output was £359,382. The total value of lands, buildings, machinery and plant was £277,422. The output in 1900 consisted mainly of 1,445,867 yards of tweed, 1,191,234 yards of flannel, 49,523 pairs of blankets, in addition to rugs, shawls, hosiery and yarn.

Clothing factories give employment to about 9,000 hands—they are too nmerous to mention under their separate headings. No cotton mills exist, but flax is dressed at 101 factories; 1,698 hands (all males) being employed. The total value of the output was £203,492 in 1900, being 6½ times the value in 1895.

Summary of Employment in Manufacturing Industries.—In all 46,847 persons, 36,292 being males and 10,555 being females, are employed in preparing food, clothing, or appliances for the use of the community and for export purposes generally. These earn in wages £3,302,647. The total value of the raw material on which they operate was valued at £7,749,770, and the value of all manufacturing produce (including repairs) stands at £17,853,133. Of the capital invested, £1,980,428 would be represented by the value of land occupied, £2,575,629 by buildings, and £3,852,457 by machinery and plant. This makes a gross total of £8,408,564. Reckoned on the mean population in 1900 of 763,594 persons, this would afford an average consumption in manufacturing industries of goods valued at £10 2s. 10d. per head of population, and an output of manufactured produce of £23 7s. 7d. per head of population.

The wealth of New Zealand is by no means expressed by the above figures. While manufactures are growing in importance, this growth has been occa

sioned by such matters as agricultural and metallurgical developments, which have also occasioned growing imports of various kinds. Before considering external trade, the indigenous industries call for consideration. The population being largely engaged in pastoral and agricultural pursuits, farm stock generally is increasing. The number of horses amounts to 298,714, the number of cattle to 1,593,547, and the number of sheep to 18,954,553. Pigs amounted to 226,591. The only decline is in regard to sheep, which fell from 20,342,277 in April, 1902, to the already quoted figure of 18,954,553 by April, 1903. A somewhat similar decline took place between April, 1895, and April, 1896. There were in 1903, 2,751 owners of flocks of sheep. Of these 2,081 owned flocks from 1,000 to 2,500, and 670 owned flocks of from 2,500 to 5,000.

Grain Crops.—The acreage of wheat under cultivation in 1903-1904 amounted to 230,436 acres, which yielded an average of 34·26 bushels per acre. Oats were cultivated upon 409,390 acres, yielding 38·57 bushels per acre. Barley, rye, and maize were cultivated to a smaller degree, the yields being 33·46; 17·00 and 47·53 bushels per acre. Of root crops, such as sown grass, 4,607,165 acres had been previously ploughed, and 7,342,006 acres had not been ploughed. Thus 5·22 per cent. of the total acreage is devoted to grain crops, 5·84 per cent. to green and other crops, and 88·49 per cent. to artificial pasturages, sown grasses and land in hay.

Gold Production.—Since 1857 the colony has produced 16,105,821 ounces of gold, valued at £63,149,147. The production reached its high-water mark in 1866, when the value of the production amounted to £2,844,517. The value fell year by year to £2,157,585 in 1870, rose to £2,787,520 in the following year, declining until 1890, when the value of the output was only £773 438. The production is now increasing and reached 533,314 ounces, valued at £2,037,831 in 1903. The number of hands employed amounted to 10,210 in 1903, of whom 477 were Chinese.

Gold mining operations are divided under three heads, (*a*) gold quartz mines, which in 1901 employed 4.333 males, who earned £382,658, the approximate value of machinery and plant being £735.927; (*b*) hydraulic gold mining, employing 962 males, paying them £76,008 for labour; and (*c*) gold dredging, employing 965 males, who earned £78,238; the value of plant and machinery being estimated at £690,430. It appears that the total revenue yielded to the Colonial Government amounted to £29,922.

Other Mineral Exports. — The value of other mineral exports is put at £858,874 for 1903. This included 911,914 ounces of silver (value £91,497); 152,332 tons of coal (value £128,927), add 9,357 tons of Kauri-gum (value £631,102). Except as regards coal, the whole of the mineral wealth appears to be exported. Out of 1,420,193 tons of coal raised, 152,332 tons only were exported, the value of the exported coal being estimated at £128,927, as against £633,931 retained for home consumption. The number of persons employed in coal mines amounted to 2,278, the large annual yield of 498 tons being secured per *employée*. The wages paid in 1901 amounted to £242,089, the number of hands then being 2,460. The approximate value of machinery and plant was then £372,093.

Export Trade as a Whole.—Excluding specie (and also the Maori population, for some reason which only the Government statisticians can explain) the exports per head of population amounted to £18 5s. 1d., or a total sum of £14,838,192. Of the export trade, goods and specie, to the value of £11,321,262, went to the United Kingdom, of £2,733,839 worth to the rest of the Empire (including Australia, £2,147,189), leaving £783,097 as the exports to the rest of the world. The United States purchased £669,649, and Germany only £17,584. Examining individual items of export, the United States purchased £362,890 worth of kauri gum, as against a British purchase of £238,083. Agricultural machinery to the value of £5,072 of local manufacture was exported, together with £6,602 worth of re-exported goods under this heading. Frozen meat went mainly to the United Kingdom under the following chief headings:—

Frozen beef........	£199,183
Frozen lamb	£1,120,716
Frozen mutton	£1,594,135

Tallow to the value of £458,851, and wool to the value of £3,998,569 were also exported to the United Kingdom.

Import Trade as a Whole.—Excluding specie the imports of New Zealand amounted to £12,075,959 in 1903. Reckoned per head of population, excluding Maoris, this amounted to £14 14s. 5d. The value of speccie imported was £712,716. Imports from the United Kingdom, including specie, amounted to £7,512,668, from Australia to £2,120,155, and from the rest of the British Empire to £1,015,319. The total imports from the British Empire, as a whole, thus amount to £10,648,142, leaving £2.140,533, or nearly 18 per cent. as coming from the rest of the world. Of this amount £1,441,358 is accounted for by the United States, and £274,297 by Germany. Considering individual items of import, chemical compounds come mainly direct from the United Kingdom, German competition being keenest in this direction. A few of the more important items are:—Acetic acid, ex United Kingdom, £1,710, ex Germany, £1,586; salicylic acid, ex United Kingdom, £82, ex Germany, £110; tartaric acid, ex United Kingdom, £3,044, ex Germany, £67; potash, ex United Kingdom, 1,087, ex Germany, 881; soda ash, ex United Kingdom, £4,760; caustic soda, ex United Kingdom, £8,102; unenumerated alkaline products, ex United Kingdom, £1,729, ex Germany, £1,140. Clothing to a value of £515,979 came from the Mother Country. Calico to the value £189,378 was imported, of which £183,296 came from the United

Kingdom, a somewhat similar proportion ruling with regard to other cotton goods.

Of iron and steel goods the United Kingdom exported the following quantities to New Zealand:—Bar, bolt, and rod iron, £107,485; pipes and fittings, £101,878; rails, £73,184; galvanized corrugated sheets, £200,657; as well as the bulk of each of the other imports under this head. As regards machinery the competition is much keener.

Agricultural Machinery.—Out of £108,310 value imported, £59,210 came from the United States, £19,753 from Canada, and £22,039 from Great Britain. Of £40,776 worth of dairy machinery, the United States sent £5,371, Sweden £15,358, the United Kingdom £4,655, and Australia £9,052. Electrical machinery came mainly direct from the United Kingdom, which supplied £47,472 out of a total of £77,413 entered subject to duty. The United States sent £9,190. Some £33,525 were entered as duty free, of which £32,566 came from the United Kingdom. Other varieties of machinery were imported from the United Kingdom to the following values: — Steam engines £11,551, gas engines £27,114, boilers £8,420, gas making machinery £23,631, mining machinery £34,210, portable and traction engines, £51,426; refrigerating, £5,436. In all these, as well as in regard to minor imports of machinery, the bulk comes direct from the United Kingdom.

Woollen Piece Goods are imported to the value of £400,206, of which £356,806 worth comes from the United Kingdom.

It is a reasonable assumption that a large proportion of goods imported into New Zealand, from Australia, come *viâ* Victoria and New South Wales. To allocate all of these as Australian in their origin, would be obviously unfair, as Sydney and Melbourne act as the *entrepôts* of a large distributing trade in British, German, and American wares. It is impossible also to assume that the imports coming from Australia in this process of distribution would bear the same definite proportionate origin as do the whole of the imports of these regions. It is probable that if the ultimate origin of all these goods were known, the predominance of the position occupied by the United Kingdom in the external trade of New Zealand might be either slightly increased or slightly decreased. In either case the change would not be a great one.

IRISH BANKING AND RAILWAY STATISTICS.

The Banking and Railway Statistics for Ireland just presented to Parliament indicate continuous and even rapid growth in material prosperity during recent years. An analysis of the tables given in the Report (Cd. 2519) gives the following results. In December, 1904, there was an increase of deposits and cash balances in the Irish Joint Stock Banks, as compared with the corresponding period of 1903, amounting to £716,000; there was an increase of £1,534,000 in deposits and cash balances in the Irish Joint Stock Banks in December, 1904, as compared with June of that year; there was an increase of £298,000 in the deposits of savings' banks in Ireland in December, 1904, as compared with the close of the year 1903, there having been an increase of £300,000 in the Post Office Savings' Banks, and a decrease of £2,000 in the amount in the Trustees Banks; there was an increase of £1,273,000 in the amount of Government Funds, Indian Stock, Guaranteed Land Stock, Guaranteed 2¾ per cent. Stock, and War Stock, on which dividends are payable at the Bank of Ireland, as compared with the amount at the close of the preceding year.

A diagram attached to the report shows the position and progress of the amounts of the deposits and cash balances in the Joint Stock Banks and the amounts of the deposits in Post Office and Trustee Banks during the forty-five years 1860–1904. The Trustees Savings' Banks show little change during that long period. In 1861 the deposits stood at £2,000,000, and they have never reached £2,500,000, the actual figures at the end of December last being £2,445,000, or £2,000 less than at the end of 1903. The Post Office Savings' Banks show a much more satisfactory growth. Established in 1862 the deposits did not exceed £2,000,000 until 1883. In 1884 there was a very slight increase but since then the growth has been much more rapid until at the end of last year they stood at £9,847,000. The deposits in Post Office and Trustee Savings' Banks nearly doubled in the decade ended December 31st, 1904.

The figures relating to Irish railway traffic are noteworthy. As given in the present report they cover the thirty years 1874–1903. In that period the total paid-up stock and share capital has only increased from £22,399,059 to £26,846,301, but the sums raised by Loans and Debenture Stock have risen from £7,443,304 to £11,116,951. The mileage has increased from 2,127 miles to 3,270, and whilst the number of passengers has increased from 16,535,578 in 1874, to 28,628,083 in 1903, there has been a large shrinkage in first and second class passenger traffic. In 1874, 1,914,181 passengers were conveyed first-class, in 1903, only 1,462,602; in 1874, 4,163,657 were conveyed second-class, in 1903 only 3,738,567. The receipts from first-class passengers fell from £273,777 in 1874 to £171,109 in 1903. On the other hand the receipts from third-class passengers rose in the same period from £584,251 to £1,170,125. The proportion per cent. of expenditure to total receipts continues very high, being no less than 61 per cent. in 1903. In 1901 it was the highest for the thirty years, namely, 63 per cent.

The report touches upon the growth of the co-operative credit associations. The organisation of co-operative credit associations in the rural districts of the South and West of Ireland was inaugurated

n 1894 by the establishment of a "bank" at Doneraile, Co. Cork. The success of this trial institution, which was founded on what is known as the Raiffeisen system, led to the creation of similar institutions in various parts of the country. The following statement shows the growth of co-operative credit associations in Ireland since 1895:—1895, 1; 1897, 3; 1900, 75; 1903, 201. The membership has grown from less than 50 in 1895 to 7,917 at the end of 1903. The total loans granted during the year 1903 amounted to £20,435 16s. 4d. The loan capital, which consists of (1) loans obtained from the Congested Districts Board, the Department of Agriculture and Technical Instruction, and the Joint Stock Banks, and (2) deposits made by members of the co-operative credit associations, amounted to £19,588, as compared with £13,956 in the previous year. The loans averaged very small sums, but the net loss on the whole of them was only £6 4s. There are no paid officials in these credit associations, all the services for management and control being given without reward. There can be no doubt that the associations are doing a good work in Ireland, as in Germany, Austria, Italy, and France. These credit associations deal only, and by their nature can only deal with a small part of the whole field of agricultural credit, but in Ireland it is a very important part.

AUSTRALIAN SILVER PRODUCTION.*

It is only within the last few years that Australia has become one of the leading silver-producing countries of the world, although the metal is to be found in all the States, either alone or in the form of sulphides, antimonial and arsenical ores, chloride, bromide iodides, and chloro-bromide of silver, and argentiferous lead ores, the latter constituting the largest deposits from which the metal is obtained. Less than twenty years ago the quantity of silver, silver-lead, and silver ore exported from Australia was trifling compared with the proportions assumed at the present time, the exports during 1903 comprising 1,033,920 ounces of silver contained in matte, 1,603,926 cwts. of silver ore, and 553,308 of silver bullion, the total being of the estimated value of £1,177,177. The whole of this was of Australian origin. In 1904 there was an increase of production in New South Wales, the exports from that State reaching the record value of £2,065,540. The two leading silver-producing States are New South Wales and Tasmania. The principal supply in the former is obtained from Broken Hill, which is also the centre of one of the largest pastoral districts in the Commonwealth. It is situated about 925 miles north-west of Sydney, near the South Australian border, the nearest port being Port Pirie, in the latter State, where smelting operations are conducted on a large scale. Broken Hill forms portion of the Barrier district, so called from a series of low hills known as the Barrier Range, and including Silverton, Thackaringa, and other argentiferous localities. The Barrier silver field extends over 2,500 square miles of country, and was discovered in 1883 by a boundary rider named Rasp. At that time hardly anything was known of the country, there being no roads and scarcely any population, but at the present time Broken Hill alone has a population of over 28,000. The leading mine, the Broken Hill Proprietary, is the most prolific silver mine in existence, the production from the commencement of mining operations in 1885 to the middle of 1904 being 7,134,526 tons of silver and silver-lead ores, from which were obtained 124,552,679 ounces of silver and 663,423 tons of lead, valued in the London market at £26,896,000. The lode is the largest yet discovered, varying from 10 feet to 200 feet in width, and traceable a distance of several miles, the country having been taken up all along the line in leases held by mining companies and syndicates. In Tasmania the principal silver fields are in the western and north-western districts, the largest output being from the Mount Lyell mine, where the metal is found in conjunction with copper. Silver is found in various parts of Queensland, mostly associated with other metals, the principal mine being at Texas, in the Stanthorpe district. There are no silver mines in Victoria or Western Australia, but this is more than compensated by their auriferous richness; the metal is, however, occasionally found associated with gold. In 1903 the value of the Victorian silver thus obtained was £2,280; that produced in Western Australia being valued at £19,153. Although the Barrier silver field approaches very closely to the South Australian border, it does not cross it, hence the silver production of that State in 1903 reached a value of only £2,071. The great difficulty hitherto experienced in the silver mining industry has been the want of some cheap and effectual method of treating refractory ores. Much has been done in this direction at Broken Hill, and practical men entertain an opinion that within the next few years the cost of extracting the silver and dealing with the other metallic contents of the ores will be reduced fully one-half if not more. The total value of the silver raised in the Commonwealth to the end of 1903 was £40,124,145, as follows:—New South Wales, £35,283,159; Tasmania, £2,872,276; Queensland, £923,725; Victoria, £864,276; South Australia, £140,441; and Western Australia, £40,425. There are rich silver deposits in the Northern Territory of South Australia, but up to the present none have been worked to any extent. In one locality extensive silver lodes have been discovered, carrying 100 ounces of silver and a large per-centage of lead to the ton. Lodes of silver-bearing ores have also been found near the Mary river, from 50 to 100 ounces per ton. Most of the lode silver comes from galena, which, as a rule, is very rich in the metal.

* Communicated by Mr. John Plummer, Sydney, New South Wales.

GERMAN MACHINE INDUSTRY.

In accordance with the general upward movement of other industrial branches at the close of the last century, the German machine industry has materially developed. During a comparatively short time many new works have been erected and old plants have been enlarged. In addition their capacity has been increased by the application of quick-turning tools, and through better working methods, so that their total capacity is estimated to have more than doubled since 1890. The home consumption is very far from being in a position to take up the entire German production. Moreover, the prevailing unfavourable economic condition is rendered more severe by the fact that the crisis, according to the United States Consular Agent at Gera, due to the introduction of large gas motors and steam turbines, has not yet fully subsided. As a consequence, many works are forced to resort to new branches and to continually expend large sums for trials and tests. Furthermore, it is stated that the new commercial treaties will prove a great drawback to the exportation of large German machines. Also fears are entertained that the strike of the miners in Westphalia will unfavourably influence the working people engaged in the machine industry, and render the relations between employers and *employés* more and more disagreeable. According to a report of the United German Engine Manufacturers, numbering about 160 of the most prominent makers, the value of the total exports of machines from Germany in 1904 amounted to about £12,900,000, which amount is expected, however, to experience a considerable reduction by the new commercial treaties. For this reason, a strong coalition of all machine manufacturers is suggested, with the object of effectually safeguarding the interests at stake, as is done now in the case of the coal and iron interests. To ensure success for every branch, the formation of groups with equal producing capacity is advised. Besides, special efforts are recommended towards attaining more advantageous commercial treaties with the United States, the United Kingdom, and Argentina. To show the disparity between the tariffs of the different nations, it is asserted that a steam engine of 3,000 horse power, and of a value of £11,500, is subject to a duty of £457 when introduced into Germany. When exported, however, to Austria, a duty is charged thereon of £1,900; to Russia, £5,500; to Italy, £1,250; and to Switzerland, £522.

ADMIRALTY CHARTS.

The following is the official list of charts issued by the Hydrographic Department of the Admiralty in March and April last:—

New Charts.—No. 3479—Baltic sea; Gulf of Finland:—channels leading to Viborg. 73—Spain, north coast:—Port Pasages. 3485—Greece, west coast.:—Port Plateali (Platea). 1198—Sea of Marmara:—The Bosporus (plan:—The Golden Horn). 3488—Iceland, north coast; Eyia (öe) fiord. 3433—Newfoundland, Bay of Exploits; Sheet II. (Middle). 3434—Newfoundland, Bay of Exploits; Sheet III. (South). 707—Madagascar, north-west coast:—Ambavatobi bay. 3486—Cochin China:—River Matshé. 951—Japan; Nipon, south coast:—Osaki wan to Owashi wan; (plans:—Goba anchorage; Kinomoto road). 3469—Japan, inland sea:—Hiroshima wan; (plans:—Ono seto; Karoto koseto). 2511—Japan sea; Russian Tartary:—Strelok bay to Mosolova point; (plans:—Uspeniya bay; Olga bay; St. Valentine bay). 3481—New Zealand:—Awarua or Bluff harbour. 3490—New Zealand, west coast South island:—Buller bay and Westport harbour. 1300—Chile; plans on the coast of:—New plan; Horcon and Quintero bays. 3313—Alaska; Yakutat bay; plan added:—Controller bay. 3136—Alaska, anchorages in; plan added:—Shearwater bay. 1457—Alaska, anchorages in; plan added:—Nateekin bay. 949—Ports in the Philippine islands; new plan:—Port Galera and Varadero bay. 981—Caroline islands; Seniavina islands; new plans:—Port Metalanim; Port Lot.

Charts that have received additions or corrections too large to be conveniently inserted by hand, and in most cases other than those referred to in the Admiralty Notices to Mariners:—

GENERAL NOTES.

JEWISH COLONIES IN PALESTINE.—In his report on the Trade and Commerce of Palestine for 1904 (No. 3410, Annual Series), Mr. Consul Dickson gives some interesting particulars respecting the Jewish colonies established in Palestine. Of these, three, namely, Mulebbis, Richon-le-Zion, and Ekron, were founded and supported by Baron Edmond de Rothschild; three, Katra, Kustinch, and Mozah, owe their origin to the Howawé-Zion Association; and the three remaining ones, Rehobot, Wady-Hanein, and Artuf, have been established and are maintained by private individuals. There are several additional Jewish colonies of importance which have been founded in Northern Palestine and Syria, and some of them have grown considerably of recent years, and may be said to be in a flourishing state. The colony of Mulebbis was founded as far back as 1879 by some Jews of Jerusalem and Jaffa, but the climate proved unhealthy, the colonists were inexperienced as farmers, their capital was too small, and they got into great straits. Baron Edmond de Rothschild then came to their assistance, and during the next twenty years he spent many millions of francs in assisting the colonists of Mulebbis, and Jewish settlers in other localities. After many vicissitudes Mulebbis is now a large and flourishing settlement. The planting of eucalyptus trees has improved the climate, and many orange gardens have been planted in consequence of the increasing demand for Jaffa oranges in the European markets. The colony numbers about 820 settlers, who own 3,000 acres of land. Richon-le-Zion is about eight miles east of Jaffa, and was founded in 1882. It has 700 inhabitants, owning 1,500 acres of land. The prosperity of the settlement depends in great measure upon the demand which its wines and brandies may find in the European markets and those of America. The wines are said to be of excellent quality, but until a short time ago the consumers were mainly members of the Jewish faith. The reputation of the wine, however, is now spreading, and the large stock of it in the transit cellars of Hamburg has proved advantageous, inasmuch as the wine has improved in a cooler temperature, and from Hamburg, as a depôt, the sale in Europe can be pushed. At Ekron the colonists first followed agriculture with good results, but being strict Jews, and refusing to sow every seventh year, in spite of permission granted by the Rabbis, the board of administration of Baron de Rothschild decided to curtail the growing of crops within certain limits, and to try the planting of fruit trees and orange groves instead. Apricots, almonds, and peaches, as well as oranges have been cultivated with success, but until now the return has been insufficient to render the colonists self-supporting. Altogether it may be said that the Jewish colonies in Palestine are now, for the most part, fairly prosperous, but even now some of them, as at Ekron, are not self-supporting.

THE GROWTH OF ROME.—In his report on the Trade of Central Italy for 1904, Mr. Consul Morgan gives some interesting figures bearing upon the growth of Rome since it became the Italian capital. In 1871, the number of its inhabitants was only 248,208, in 1904 they had more than doubled, being 503,857. The number of births in 1871 was 6,940, and of deaths, 9,073, and the respective numbers in 1904 were 12,187 and 9,957. So that whilst the births had almost doubled, the deaths had increased by no more than 10 per cent. The death-rate which in 1871 was no less than 41·8 per 1,000 inhabitants, had fallen in 1904 to 19·7. A firm of Belgian bankers have recently formed a company with the object of building an electric railway line between Rome and Civita Castellana. The capital of the company is £140,000. The distance between Rome and Civita Castellana by the existing railway line is about 50 miles, and the proposed new line, which follows a regular and direct tract, will shorten that distance by 15 miles.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, JULY 3...Faraday Society (at the Institution of Electrical Engineers), 92, Victoria-street, S.W., at 8 p.m. 1. Mr. Sherard Cowper-Coles, "Some Notes on the Rapid Electro-deposition of Copper." 2. Prof. W. W. Haldane Gee, "The Use of Balanced Electrodes." 3. Messrs. H. D. Law and F. Mollwo Perkin, (a) "Electrolytic Oxidation of Hydrocarbons of the Benzene Series." Part I.—"Ethyl Benzene, Cumene and Cymene"; (b) "Electrolytic Analysis of Antimony." 4. Messrs. R. S. Hutton and J. R. Beard, "Notes on Heat Insulation, particularly with regard to Materials used in Furnace Construction."

TUESDAY, JULY 4...SOCIETY OF ARTS, Conversazione in the Gardens of the Royal Botanic Society, Regent's-park, N.W., 9 p.m.

Horticultural, Vincent-square, Westminster, S.W., 3 p.m. Prof. H. J. Webber, "The Progress of Horticulture in the United States."

WEDNESDAY, JULY 5...Royal Archæological Institution, 20, Hanover-square, W., 4 p.m. Mr. Charles Lynam, "A Short Note on Chepstow Parish Church."

THURSDAY, JULY 6...East India Assoc., Caxton hall, Westminster, S.W., 4 p.m. Sir David Barr, "Hyderabad—Past and Present."

FRIDAY, JULY 7...Art Workers' Guild, Clifford's-inn Hall, Fleet-street, E.C., 8 p.m. Mr. Strang, "A Method of Portrait Drawing."

Journal of the Society of Arts.

No. 2,746. VOL. LIII.

FRIDAY, JULY 7, 1905.

NOTICES.

ALBERT MEDAL.

The Council of the Society attended at Marlborough House, on Wednesday, the 5th inst., when His Royal Highness the Prince of Wales, President of the Society, presented the Albert Medals for 1904 and for 1905.

The Medal for 1904 was awarded to Mr. Walter Crane, "in recognition of the services he has rendered to Art and Industry by awakening popular interest in Decorative Art and Craftsmanship, and by promoting the recognition of English Art in the forms most material to the commercial prosperity of the country."

The Medal for 1905 was awarded to the Right Hon. Lord Rayleigh, O.M., D.C.L., Sc.D., F.R.S., "in recognition of the influence which his researches, directed to the increase of scientific knowledge, have had upon industrial progress, by facilitating, amongst other scientific applications, the provision of accurate electrical standards, the production of improved lenses, and the development of apparatus for Sound signalling at sea."

The members of Council present were Sir William Abney, K.C.B., D.C.L., Sc.D., F.R.S. (Chairman), Sir Steuart Bayley, K.C.S.I., C.I.E., Sir George Birdwood, K.C.I.E., C.S.I., Sir James Blyth, Bart., Major-General Sir Owen Tudor Burne, G.C.I.E., K.C.S.I., Sir William Crookes, Sc.D., F.R.S., Dr. Francis Elgar, F.R.S., Mr. Robert Kaye Gray, Sir Charles Hartley, K.C.M.G., Col. Sir Thomas Holdich, R.E., K.C.M.G., K.C.I.E.. C.B., Sir William Lee Warner, K.C.S.I., Sir Gilbert Parker, D.C.L., M.P., Sir Westby Perceval, K.C.M.G., Sir William H. Preece, K.C.B., F.R.S., Sir Owen Roberts, D.C.L., Sir Marcus Samuel, Bart., Mr. Alexander Siemens, Sir Boverton Redwood, Mr. Carmichael Thomas, Sir John Wolfe-Barry, K.C.B., F.R.S., with Sir Henry Trueman Wood, M.A. (Secretary, and Mr. Henry B. Wheatley (Assistant Secretary).

CONVERSAZIONE.

The Society's Annual Conversazione was held in the gardens of the Royal Botanic Society, Inner Circle, Regent's-park, on Tuesday evening, 4th inst.

The reception was held by Sir WILLIAM ABNEY, K.C.B., D.C.L., F.R.S., Chairman, and the following Members of Council:—Sir Mancherjee Bhownaggree, K.C.I.E., M.P.; Sir William Bousfield, LL.D.; Major-General Sir Owen Tudor Burne, G.C.I.E., K.C.S.I.; Dr. Francis Elgar, F.R.S.; Mr. Robert Kaye Gray; Mr. Henry Graham Harris; Sir Charles Hartley, K.C.M.G.; Colonel Sir Thomas Holdich, R.E., K.C.M.G., K C.I E., C.B.; Sir Boverton Redwood; Sir Owen Roberts, D.C.L.; Mr. Alexander Siemens; Mr. Carmichael Thomas; Professor J. M. Thomson, LL.D., F.R.S.

A Selection of Music was performed by the String Band of H.M. Royal Artillery (Conductor, Cavaliere L. Zaverthal, M.V.O.) in the Conservatory, and by the Band of H.M. Grenadier Guards (Mr. A. Williams, Mus. Bac., Oxon) in the Gardens.

Two performances of Selections from Pastoral Plays were given in the Gardens by Mr. Patrick Kirwan's Idyllic Players.

A Concert and Entertainment by members of Mr. Kirwan's Company of Idyllic Players, with Choruses by Children, was given in the Club House.

An Exhibition of Growing and Cut Roses and other Flowers was arranged in a marquee in the grounds by Messrs. W. Paul and Sons, of Waltham-cross.

An Exhibition of Economic Plants, &c., grown in the Gardens of the Royal Botanic Society, together with specimens from that Society's Museum, were on view in the Corridor.

The Tropical House, containing the giant water lily (Victoria Regia), &c., was open to visitors.

The number of visitors attending the Conversazione was 2,335.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

INTERNAL COMBUSTION ENGINES.

By Dugald Clerk, M.Inst.C.E.

Lecture I.—Delivered February 13th, 1905.

Syllabus.

Fundamental Principles. — Internal combustion engines essentially air engines — Thermodynamics air engines—Two types, constant volume and constant pressure — Theory of compression — Efficiencies without heat or other losses—Gaseous explosions—Measurement of temperature in gaseous explosions—Bunsen's method—Coal gas, petrol, cohol, and producer gas explosions — Data still uired.

An internal combustion engine is a heat engine in which the working fluid is atmospheric air, and the fuel is an inflammable gas or vapour. It differs from a hot air or steam engine in one important point, that is, the heat to supply the motive power is given directly to the working fluid by combustion within the motor cylinder.

It has long been recognised that the air engine presents many points of advantage over the steam-engine in enabling much higher efficiencies to be obtained than are possible with steam boilers and engines. Nearly all the great men who founded the science of thermodynamics, about the middle of last century, recognised this fact, and many attempts were made to realise the advantages of the air engine. Some were very bold and able, and, for the time, may be considered partially successful.

So long ago as 1854, the late Professor Rankine read a paper before the British Association "On the Means of Realising the Advantages of the Air Engine," in which he expressed his belief that such engines would be found to be the most economical means of developing motive power by the agency of heat. In this opinion he stood by no means alone. Engineers so able as Stirling, Ericsson, physicists so distinguished as the late Dr. Joule and Lord Kelvin, happily still with us, devoted much time and study to their theory and practice.

Many attempts were made, long before 1854, to carry such ideas into practice; and my friend, Mr. James Forrest, has recently presented me with prints of three papers read at the Institution of Civil Engineers in 1845, 1853, and 1855. The first paper is by James Stirling, the son of the original inventor, Dr. Stirling. It is upon "Stirling's Improved Air Engine." The second document, dated 1853, includes three papers—one by Charles Manby, another by James Leslie, and a third by William Siemens, so well known in connection with this and other subjects later on. The third document is entitled "On the Use of Heated Air as a Motive Power," by Benjamin Cheverton, dated 1855. This document also includes a paper by Sir George Cayley. The discussion on these papers includes many distinguished names, among them Armstrong, Rennie, Siemens, Bidder, Faraday, Brunel, Hawksley, Fitzroy, Braithwaite, and Robert Stephenson.

Even so long ago, then, as the middle of last century, it may be said that abundant engineering and scientific talent had been brought to bear upon this important question, and a general agreement of opinion, even then, existed, to the effect that air engines should be more economical of fuel than steam engines.

Notwithstanding all the efforts of these distinguished men, aided by a host of less able but equally enthusiastic inventors, the difficulties of the task proved too formidable, and it may be said that the hot air engine proper has made no real advance.

It was very early recognised that one leading difficulty was found in the very slow transfer of heat through metal to air. Ericsson and Sir George Cayley recognised this difficulty very early in the day, and they attempted to overcome it by what may be called internal combustion, that is, they heated their air by forcing the air through an enclosed furnace, and then passing it into the engine cylinder. These attempts, however, also failed, because of the heat loss in passing through valves, and the difficulty of keeping valves exposed to high temperatures sufficiently pressure tight.

The modern internal combustion engine differs from these crude attempts by invariably conducting the combustion within the cylinder, and burning only vapour or gaseous fuel. The method of heating by combustion or explosion at once disposes of all these troubles. It not only widens the limits of the temperatures at command almost indefinitely, but the causes of failure with the old air heating methods become the very cause of success with the new. The difficulty of heating even the greatest masses of air is quite abolished. The rapidly moving flash of chemical action makes it easy to heat any mass, however great, in a minute fraction of a second; and when once heated

the comparatively gradual convection makes the cooling a very slow matter. The conductivity of air for heat is but slight, and both losing and receiving heat from enclosing walls are carried on by a process of convection, so that the larger the mass of air which is used, the smaller is the relative cooling or heating surface. From this it follows that the larger the volume of air used, the more economical is the new method, and the more difficult is long as we keep in mind that corrections have to be made, in applying the ideas gained from air engine reasoning to practice, it will be better first to treat of our subject as if we were dealing with air only as the working fluid, and consider the air as heated by combustion without changing its chemical or physical properties. Therefore I will deal first with the thermodynamics of the internal combustion motor, considered as an air engine pure and

FIG. 1.

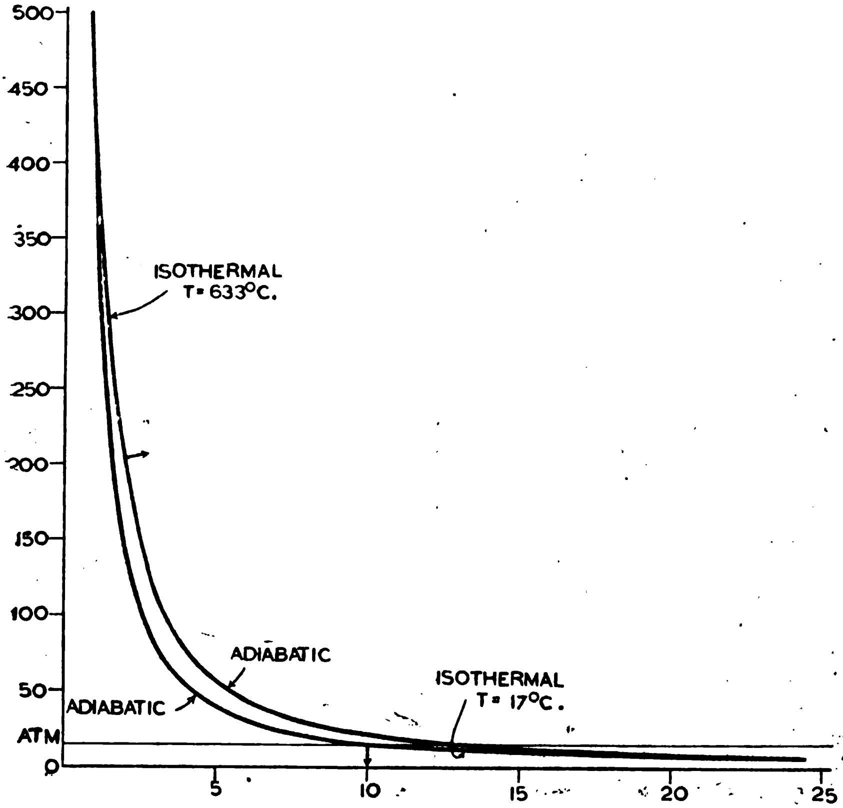

DIAGRAM FROM AIR ENGINE OPERATING ON CARNOT CYCLE.

Maximum pressure = 500 lbs. per sq. in.; mean pressure = 6 lbs. per sq. in.; maximum temperature = 633° C.; efficiency = ·64.

the old. The low conductivity for heat which was the cause of so much trouble in hot air engines becomes the unexpected cause of economy in the modern motors.

It is quite true that the internal combustion engine differs in many respects from an air engine pure and simple, yet it will be more convenient to consider these engines as simply air engines in the first instance, so as to avoid certain complexities of thought introduced by the chemical changes due to combustion. So simple. In all modern motors of this type, whether they be operated by coal gas, petrol, alcohol, or producer gas, one feature is invariably found. That feature is the compression of the working fluid before combustion. Although all engine builders use this compression, even now the true function of compression is not always clearly understood.

Over twenty years ago, a perusal of the engineering journals, and a consideration of some decisions in Patent actions in the

Law Courts, will show what ludicrously erroneous notions were held upon this subject. It was supposed that the advantage given by compression was due to the use of what was called stratification in the gas engine, and the supposed possibility of firing dilute combustible mixtures without shock. This fallacy was shared by quite a number of distinguished men, and the true theory of compression was enunciated for the first time in a paper read by me before the Institution of Civil Engineers in the year 1882. It was there pointed out that compression gave a cycle of operations having a distinct thermodynamic advantage, apart from all considerations of heat losses. It is often said that compression is only useful as a means of gaining a great expansion with a small cylinder volume, and this statement is no doubt partly true. It does not, however, express by any means the entire truth. There is much more in compression than this. Compression is advantageous not only because it allows of higher operative pressures for given temperatures and higher expansions, but also because compression forms an essential part of the operation of any ideally perfect heat engine.

It has long been recognised that an engine operating upon what is called the Carnot cycle gives the highest conversion of heat possible between the available temperature limits. The diagram, Fig. 1, shows what occurs in an engine operating in accordance therewith. In order to be explicit, I have calculated out this diagram for an engine operating with a maximum pressure of 500 lbs. per square inch absolute, using pure air as the working fluid. On the diagram you will observe two lines, one marked "isothermal," and the other marked "adiabatic." I need hardly state that an isothermal line in this connection is an expansion or compression line, where the temperature of the working fluid remains constant, and that an adiabatic line is a line of compression or expansion, where no heat is either added to or abstracted from the working fluid, where consequently temperature rises during compression, and falls during expansion. With an air engine operating in this manner the proportion of heat converted into work is very easily calculated. All the heat is added at the upper temperature, and all the heat discharged at the lower temperature, It can be readily shown that the efficiency is

$$\frac{T - T^1}{T}$$

T being the upper temperature, and T^1 the lower temperature. The proof of this statement is to be found in every engineering work dealing with thermodynamics. Such an engine converts all heat into work which can be converted. As you know, the second law of thermodynamics, on which the reasoning from

FIG. 2.

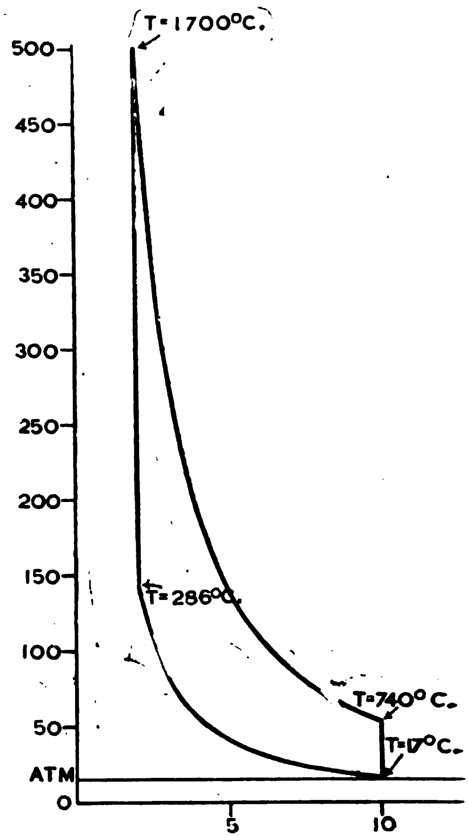

DIAGRAM FROM AIR ENGINE OPERATING ON OTTO CYCLE.

Maximum pressure = 500 lbs. per sq. in.; mean pressure = 105 lbs. per sq. in.; $\frac{1}{r} = \frac{1}{5}$; efficiency = ·48; maximum temperature = 1,700° C.; compression temperature = 286° C.; exhaust temperature = 740° C.; minimum temperature = 17° C.

the Carnot cycle is based, proves that only a certain proportion of the total heat given to any working fluid can be converted into work, and that proportion depends upon the difference between the higher and lower temperatures. Under the diagram, Fig. 1, I have marked the principal data, including the higher and lower temperatures, the maximum pressure, and the mean pressure. Also the

volume swept by the piston, taking the volume swept for adiabatic compression as unity. From these figures you will see that although the efficiency is the maximum possible within the temperature limits, the performance, that is, the actual amount of work obtained from the engine for a given size of cylinder, is exceedingly low.

Although the maximum pressure is 500 lbs. per square inch, the mean available pressure is only 6 lbs. per square inch for the particular case shown. The efficiency is high, ·64, but obviously an air engine following the Carnot cycle would be useless for all practical purposes, as the mean pressure is so low in proportion to maximum pressure.

In a recent discussion by Professor Callender, he calls the Carnot cycle a constant temperature cycle. At Fig. 2, there is shown a diagram having a similar maximum pressure. This diagram represents that which would be given by an air engine following closely all the conditions of the best known modern types of internal combustion engine, viz., the Otto, or four stroke cycle. In this engine, there is compression of air from maximum to minimum volume without gain or loss of heat; addition of heat at minimum volume, rising from temperature of compression to maximum temperature; expansion without gain or loss of heat to maximum volume; and discharge of heat at maximum volume to original temperature. For the purpose of reasoning clearly, I assume that all heat additions and abstractions are made at constant volume in any manner you may conceive possible. It is better to think of the same mass of air always in use, alternately heated and cooled at constant volume, and alternately compressed and expanded adiabatically. I should say that in both adiabatic compression and expansion, I have assumed the ratio between specific heat at constant volume and constant pressure to be 1·408, so that the equation of each curve is $PV^{1\cdot 408}$ = constant. I also assume the specific heat of air to be constant throughout the whole temperature range, and the addition and abstraction of heat to be made without chemical complications.

Under this diagram I have marked the leading particulars, including maximum and minimum temperatures, maximum and mean available pressures.

Here you will observe that with the same maximum pressure as in the Carnot cycle, and a very usual maximum temperature (1,700°C.) the mean available pressure is 105 lbs. per square inch, and the efficiency is ·48. Here the efficiency it is true is lower, but the available pressure bears a reasonable proportion to the maximum pressure, and the cycle is a thoroughly practical one.

If one considers this diagram carefully it will become evident that as both compression and expansion lines are adiabatic, that is, there is no heat addition or abstraction in the working fluid during compression and expansion, the proportion of heat converted into work of that given to the engine is correctly shown by the temperature rise on what I may

FIG. 3.

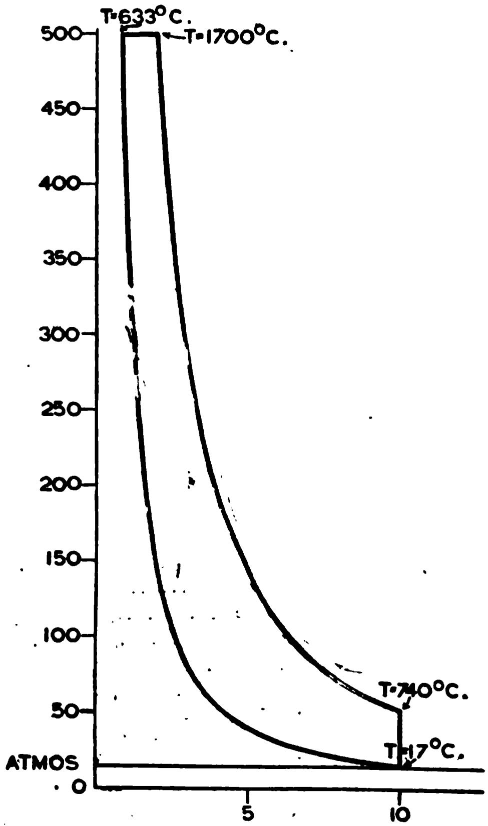

DIAGRAM FROM AIR ENGINE WITH HEAT ADDED AT CONSTANT PRESSURE AND HEAT DISCHARGED AT CONSTANT VOLUME.

Maximum pressure = 500 lbs. per sq. in.; mean pressure = 117 lbs. per sq. in.; maximum temperature = 1700° C.; compression temperature = 630° C.; exhaust temperature = 740° C.; minimum temperature = 17° C.; $\frac{1}{r} = \frac{1}{12\cdot 24}$; efficiency = ·61. (If expansion is carried to original pressure, efficiency = ·64.)

call the heat-addition line, as compared with the temperature fall on the heat abstraction line; that is, in this case the efficiency is also

$$\frac{T - T^1}{T}$$

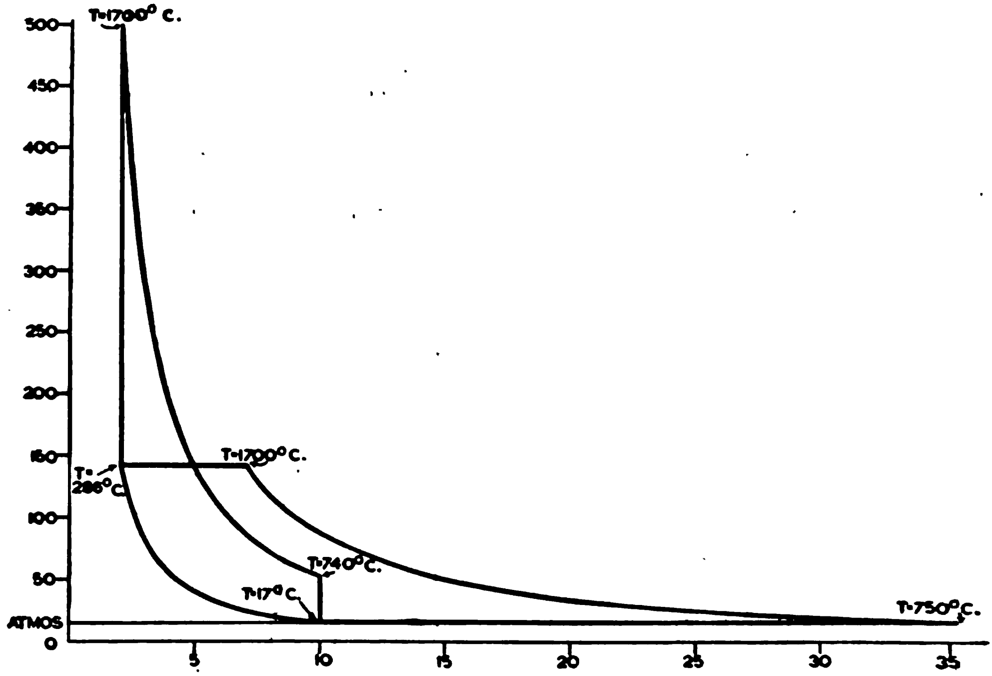
in this case, however, T being maximum temperature of heat addition, and T¹ the maximum temperature of heat discharge.

of compression. From this it follows that the efficiency can be expressed in terms of the volume before and after compression; and this worked out gives the efficiency formula as—

$$E = 1 - \left(\frac{1}{r}\right)^{\cdot 405}$$

In this particular case, $\frac{1}{r}$ is equal to $\frac{1}{5}$.

FIG. 4.



DIAGRAMS FROM CONSTANT VOLUME AND CONSTANT PRESSURE CYCLE AIR ENGINES.

	Constant Volume.	Constant Pressure.
Maximum temperature	1,700 C.	1,700° C.
Maximum pressure	500 lbs. per sq. in.	141·1 lbs. per sq. in.
Mean pressure	105 lbs. „	37 lbs. „
Efficiency	·48	·48

From the formula—

$$PV^{1\cdot 406} = \text{const.}$$

the value of the temperature at both ends of the diagram can be readily calculated for different maximum temperatures; and if you try various maximum temperatures you will at once find that on this particular cycle of operations the efficiency is the same for all maximum temperatures above the temperature of adiabatic compression; that is,

$$E = 1 - \frac{T^1}{T} \text{ or } 1 - \frac{t}{tc}$$

that is, the efficiency can be expressed in terms of the temperature before and after compression, and is independent of the increase of temperature above the temperature

and the efficiency would be ·48, that is, if 100 units of heat be given to an engine operating on this cycle, with these proportions, 48 of these heat units would be converted into mechanical work.

At Fig. 3 I have shown another diagram, which resembles the last two diagrams in one feature. The maximum pressure is the same. In this case, however, adiabatic compression has been carried to the maximum pressure, and heat is added, not at constant volume, but at constant pressure. In this diagram the engine performs the following operations:—Compression of initial volume of air to desired compression pressure, without gain or loss of heat, addition of heat to maximum tempera-

ture at the pressure of compression during expansion for a certain period; expansion without gain or loss of heat to initial volume, and discharge of heat at initial volume during fall of temperature to initial value.

Here a very high mean pressure is obtained, and the efficiency is but little lower than that given by the Carnot cycle. If the expansion in this case be carried far enough to cause the pressure to fall to the initial value, then the compression. This diagram clearly shows the relationship between the two cycles for the same compression and the same maximum temperature. In this case it will be observed that a greater expansion is necessary to obtain the same efficiency in the constant pressure case, and that in this constant pressure cycle the maximum pressure is lower. In this constant pressure cycle also the efficiency is the same for all heat additions above the tempera-

FIG. 5.

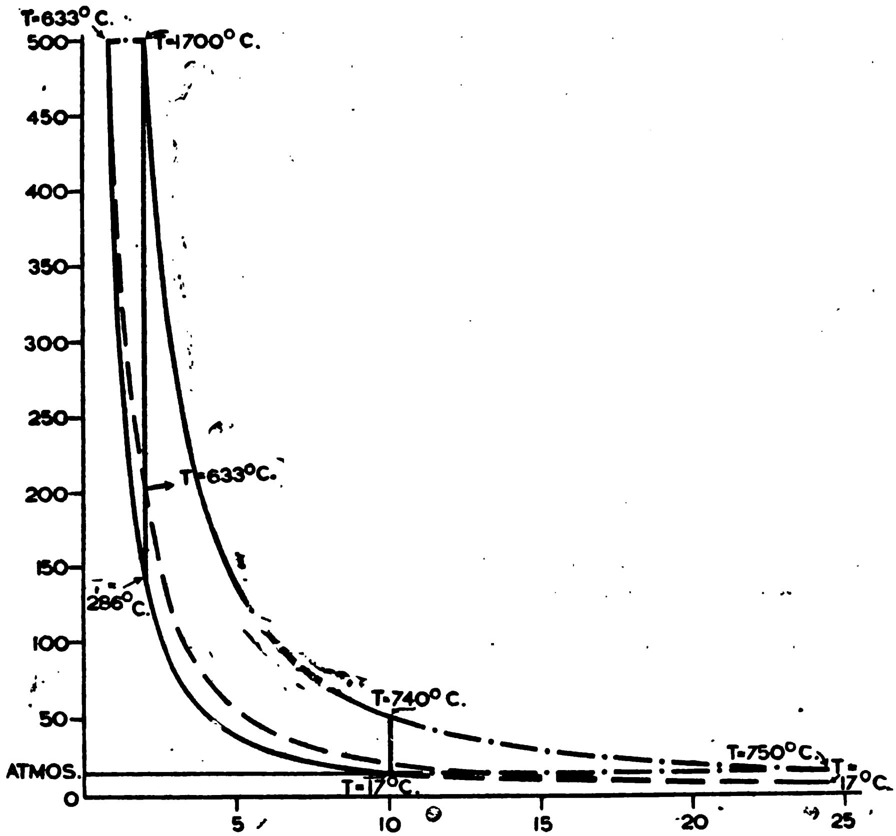


DIAGRAM FROM CARNOT, CONSTANT VOLUME AND CONSTANT PRESSURE CYCLE AIR ENGINES.

efficiency is given by the same formula as the constant volume cycle. It is ·64. The mean pressure, however, is much lower: it is only 56 lbs.; so that although there is a greater heat conversion, the engine is much heavier for the power.

This cycle may be called the constant pressure cycle, because in a perfect example heat is added and discharged at constant pressure.

Fig. 4 shows a constant volume cycle, such as is seen at Fig. 2, combined with a constant pressure cycle arranged for the same ture of compression, the condition of maximum efficiency for these circumstances being expansion to atmosphere. It is interesting to note that here we have the same efficiency formula for the constant volume and constant pressure cycles, the efficiency depending on the compression ratio only. The fact that these efficiencies were the same was first recognised by me in 1882, and for many years other engineers, notably M. Witz, of Lille, have also recognised this interesting fact.

Only a few weeks ago, however, Professor Callender pointed out that even in the Carnot cycle the efficiency is determined by the adiabatic compression line, and that it also has the same value for a given compression as is found for either constant volume or constant pressure cycles.

Fig. 5 gives a combined diagram, in which Carnot, constant volume and constant pressure cycles are shown, the feature common to the whole three, however, being that the maximum pressure is the same. In this case the Carnot cycle and constant pressure cycle have the same efficiency; but the constant volume cycle has a less efficiency. These diagrams, with the details marked under them, will prove useful to engineers designing gas engines, as showing pressures which would be given by ideal air engines corresponding closely to the different types; but the most interesting and important, from the manufacturing engineers' point of view, is, of course, that dealing with the efficiency of the constant volume cycle. This is the cycle which is followed in the majority of cases now. Only one constant pressure engine appears to be upon the market at present, viz., the Diesel oil engine.

Fig. 6 is a diagram which illustrates to you the efficiencies of constant volume engines at different compressions. A range of three diagrams is shown, in which the heat additions are all equal to one another, and equal to the heat addition illustrated in Fig. 2. This diagram at once shows clearly to the eye the fact that, as compression increases, greater conversion of heat into work results. This can be calculated from the formula:—

$$E = 1 - \left(\frac{1}{r}\right)^{\cdot 408}$$

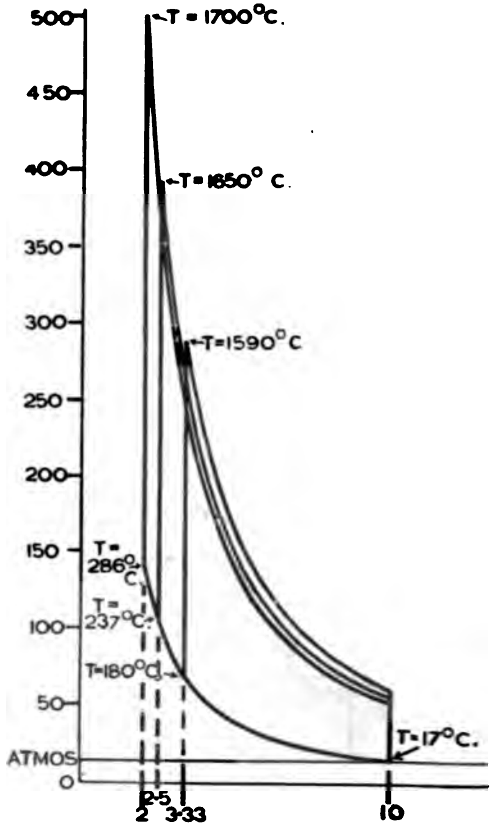
and I have made a calculation for the following values of $\frac{1}{r}$:—

TABLE I.

$\frac{1}{r}$	E
$\frac{1}{2}$	·246
$\frac{1}{3}$	·36
$\frac{1}{4}$	·43
$\frac{1}{5}$	·48
$\frac{1}{7}$	·55
$\frac{1}{10}$	·61
$\frac{1}{20}$	·70
$\frac{1}{100}$	·85

From these calculations it becomes at once evident that there is a very large thermodynamic gain, due entirely to increased compression or diminished compression space volume. The efficiencies range from compression space equal to $\frac{1}{2}$, giving an efficiency of ·246, up to compression space equal to $\frac{1}{100}$, giving an efficiency of ·85. These of course are efficiencies which could only be obtained in an ideal engine, assumed to exist without heat

FIG. 6.



DIAGRAMS FROM OTTO CYCLE AIR ENGINES AT DIFFERENT COMPRESSIONS.

	Maximum pressure per sq. in.	Mean pressure per sq. in.	Efficiency.
$\frac{1}{r} = \frac{1}{5}$	500 lbs.	105 lbs.	·48
$\frac{1}{r} = \frac{1}{4}$	391 lbs.	101 lbs.	·43
$\frac{1}{r} = \frac{1}{3}$	287 lbs.	97 lbs.	·36

losses of any kind, working with air having a constant specific heat, and so operated that no valve losses or throttle losses were incurred. I need not tell you that no actual engines give efficiencies so high as these for any given compressions.

I have already said that the increase of thermodynamic efficiency due to compression

is caused by something more than the increased expansion which is obtained. At first sight one would think that if a great enough expansion could be obtained with an explosion, say starting at atmospheric pressure, the same results should be given as we get with a corresponding compression and equivalent expansion. This, however, is not the fact. Mere expansion does not give the efficiencies obtained by adiabatic compression and then expansion. This appears to be due to the fact that by compressing a gas without loss or gain of heat, either at constant volume or constant pressure, the whole of the heat absorbed during the subsequent ignition is utilised for the purpose of doing the available work of expansion. This may be clearly seen by considering the case of an engine compressing not on an adiabatic line, but on an isothermal line. In this case, in addition to the heat added for doing the available work of expansion, there is a large proportion of heat added for doing that part of it which is unavailable. The reasons why compression, then, produces such great economies, are: (1) it allows of large range of expansion, and (2) it allows of the heat which is added being available for producing the work of the actual indicator diagram. It is somewhat difficult to grasp the abstract reason for the increase of efficiency due to compression, it will, however, from the above considerations, be clearly seen that adiabatic compression forms the basis of all perfect or approximately perfect heat engines. In actual practice, of course, there are other advantages than those flowing from increased efficiency. Compression enables high pressures to be generated within the cylinders, and so reduces the bulk of the engine. It further diminishes the proportional heat losses, and so tends to economy in the practical engine.

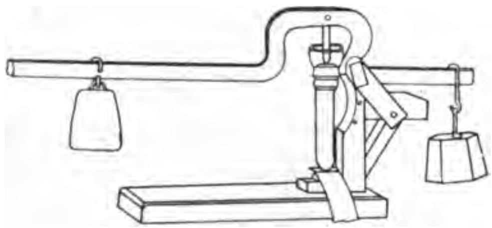
Before considering the question of actual efficiencies in engines, it is desirable to understand to some extent what goes on in a gaseous explosion.

If air at a temperature of 0°C. and atmospheric pressure be confined within a closed space, say a closed vessel, and then heated, for every increase of temperature of 1°C., the pressure will increase by 1/273; that is, when the temperature is raised to 273°C., the pressure within the vessel will have increased to 2 atmospheres. At a temperature of 546°C. the pressure would be 3 atmospheres; and the pressure will continue rising with the temperature, so that at a temperature of 2,184°C. the pressure of our confined air will have risen to 8 atmospheres. This increase of pressure will occur in whatever way the air be heated. The air might be heated by heating the enclosing vessel; or by heating by means of, say, electric currents passing through platinum wires, or by internal combustion. This is practically what happens when gas is mixed with air, and the mixture then ignited within a closed vessel.

Professor Bunsen, the great German chemist, long ago proposed this method of determining the temperature produced by gaseous explosion.

Fig. 7 shows the apparatus which Bunsen

Fig. 7.



Bunsen's Apparatus for determining the Temperature of Explosion.

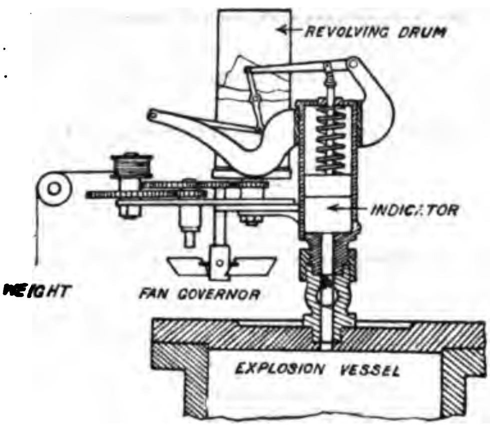
used in the year 1866. Bunsen enclosed a certain volume of explosive mixture in the small tube shown in that figure, and he weighted a valve which closed the upper part of the tube, so that the valve just blew off when the mixture was exploded by an electric spark. The pressure at which the blow-off took place he considered to be the maximum pressure of the explosion, and from that pressure, calculating exactly in the way I have described, he determined the temperature of the explosion flame.

Many years ago, I made experiments similar to Bunsen's by means of an apparatus shown at Fig. 8; and recently I have made experiments with a new apparatus of a different type, the results of which I show at Fig. 9. The apparatus consisted of a cylinder having strongly bolted covers. Upon the upper cover is placed a Richards indicator, and the pencil acts upon a rotating drum, which drum is operated by clockwork, and a record is produced which is afterwards copied from the drum. The rising line which you see traces the progress of the explosion, and the falling line the progress of the cooling. The rate of revolution of the drum being known, the interval of time elapsing between the periods of the explosion or cooling curve is also known. These experiments clearly proved that a

gaseous explosion produces a maximum temperature close upon 2,000°C., and this temperature is produced by pressure slightly over 100 lbs. to the square inch above atmosphere. These experiments were first published by me in 1886.

To get quite accurate results, it is necessary

FIG. 8.



CLERK EXPLOSION APPARATUS.

to allow for chemical expansion or contraction, and this question of chemical expansion or contraction is the principal one, apart from heat value, which determines the difference in behaviour of different gaseous explosions.

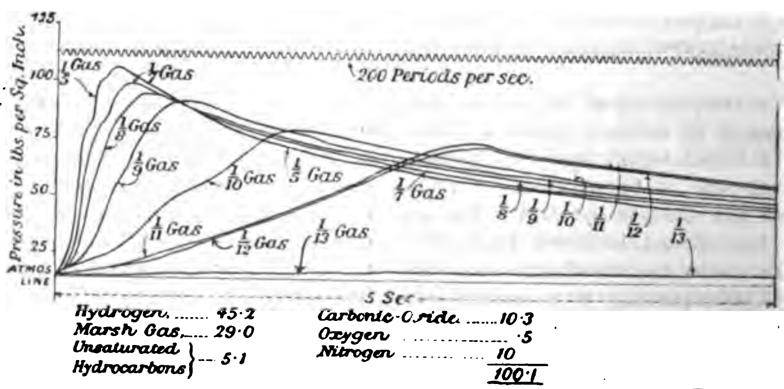
So far, most of the work which has been done on gaseous explosions with a view of determining the maximum temperature and cooling curve for different mixtures, have been made with coal gas and air mixtures. Little is known of the cooling curve of petrol, alcohol, and producer gas explosions, except from the behaviour of such gaseous mixtures in the engines.

Table II., however, shows the difference which may be expected from these explosions, so far as chemical contraction is concerned. One feature, however, stands out clearly in connection with all these gaseous explosions. That feature is, the apparent suppression of part of the heat of the gas or vapour present at the maximum temperature of the explosion; that is, if the maximum temperature of the explosion be calculated, and it be assumed that the specific heats of the products are constant, then it will be found that the heat evolved by the temperature rise is not equal to that of the gas present. This fact has led to a great deal of discussion among engineers, chemists, and physicists. Some, including many French experimenters, say that the specific heat of air and other gases changes largely at high temperatures, and that the whole heat is evolved at a maximum temperature, but specific heat varies. Others say that the explosion experiments cannot prove this, and that although maximum temperature is obtained, combustion is not completed at that temperature, but goes on for some time after maximum temperature. Others, again, say that dissociation of carbonic acid and water intervenes, and prevents further evolution of heat till temperature falls.

In discussing the application of the theory of compression to the actual efficiencies of internal combustion motors, it is desirable so to arrange matters as to avoid the necessity for accepting any particular theory. In these lectures I propose to do this.

It is desirable, however, always to bear in mind that although for simplicity's sake we discuss internal combustion engine problems as if we had to do with an air engine pure and simple, yet in considering the actual conditions

FIG. 9.



CLERK EXPLOSION CURVES FOR VARIOUS MIXTURES OF LONDON COAL GAS.

of practically operating engines, the problem is very much more complex. The amount of heat not accounted for by the temperature rise in gaseous explosions, assuming constant specific heat, varies from 30 to about 50 per cent., depending upon the strength of the explosive mixture. If the mixture be approaching the maximum flame temperature, then a large proportion of heat remains unaccounted for. On the other hand, if the mixture be approaching the point of missing firing by over dilution, then heat unaccounted for is equally great. The greatest proportion accounted for is found with intermediate mixtures, such as mixtures of coal gas and air ranging from 1 in 10 to 1 in 12. These are the mixtures which are most economically used in coal gas engines. To understand the conditions of economy, however, it is well to simplify the problem as much as possible. The diagrams reproduced above are the diagrams which a pure air engine would produce, if the specific heat of air were constant at maximum temperature, and if no heat losses whatever were incurred by the contact of the flame with the cylinder; and, further, if no valve losses were incurred, due to throttling during admission, or back pressure during exhaust. These matters I propose to deal with in the next lecture; but meantime we shall confine ourselves to the simplified problem, assuming certain heat losses.

Taking, for example, the constant volume engine, of which the diagram is shown at Fig. 2, this engine, as you see, without heat or other losses, would convert 48 out of every 100 heat-units given to it into indicated work. Assume now one simple case of heat loss, that is, heat loss during the expansion stroke only; and assume a phenomenon similar to the actual case in the gas engine cylinder, that is assume the expansion line to be apparently adiabatic, although in reality heat is flowing away to such an extent that an equal quantity requires to be added during expansion to that which is added at the beginning of the stroke. In this case, it is evident that the calculation for the actual efficiency of the engine is a very simple one. Instead of adding 100 heat-units, 200 have been added, and from these 200, only the work shown upon the diagram has been given. The practical efficiency of this engine would therefore be given by multiplying the ideal efficiency by ·5, that is, half of the ideal efficiency would give the practical efficiency.

If the expansion line be above the adiabatic, the problem is by no means so simple, because here, even without heat loss, the efficiency of the expansion is greatly reduced.

In the James Forrest Lecture, which I had the honour of delivering to the Institution of Civil Engineers last year, I calculated a number of cases of this kind, and showed that the efficiency suffers considerable reduction by the addition of heat in the expanding line, to keep up an expansion above the adiabatic. In a case of this kind—a case which indeed occurs in practice in large gas engines—it is necessary to calculate the efficiency on the assumption of expansion above the adiabatic, in order to find the real efficiency of the engine which is under examination.

The other engine cycle, *i.e.*, the constant pressure cycle, is one which is also subject to heat loss, but as a considerable part of the work is done during increasing temperature, the heat loss per stroke is somewhat less than in the constant volume cycle, and accordingly some advantage results.

Much has yet to be done, before all the actions going on in the cylinder of the internal combustion motor can be fully understood; and if we hold clearly in our minds the efficiencies possible with engines suffering no heat losses, subject to no complications as to chemical action or change of specific heat, we shall hold a key which will guide us through many complexities, and will supply clear indications of the line of advance. To advance quickly, it is necessary to understand fully, and many experiments yet remain to be made to enable us to understand the peculiarities of the numerous different gaseous and vapour explosions now utilised in these engines. Experiments have still to be made upon the specific heat of the products of combustion at high temperatures, the laws of cooling of the flames within the cylinders, the laws of combustion, proceeding at the enormous rates experienced in these engines. Especially urgent is the requirement for explosion and cooling curves for coal gas, petrol, alcohol, producer gas, and blast furnace gas explosions. Some of these matters, however, I propose to deal with in considering the indicator diagram in my next lecture.

BRITISH TRADE IN SIBERIA.

It is just two years since Mr. Henry Cooke left Moscow for Siberia, to inquire into and report upon the present position and future prospects of trade in Siberia, more especially with reference to openings for British enterprise. Mr. Cooke undertook his mission on behalf of the Commercial Intelligence Department of the Board of Trade, and the outbreak of war between Russia and Japan so altered the conditions prevailing in a great part of the country visited that the Board of Trade thinks no good purpose would be served at present by publishing the results of Mr. Cooke's inquiries so far as relates to the Far East. Accordingly, the present Report is entirely confined to Siberia, west of Lake Baikal. It is a voluminous and highly interesting document, and deserves the very careful consideration of business men. The Report is calculated to dispel the associations with which Siberia has hitherto been almost exclusively connected, and to encourage Englishmen in search of new markets and trade openings to personally examine, in the country itself, the possibilities it presents. The American, the Dane, and the German are there already, and have captured some of the most fruitful fields it affords for enterprise. If what remains does not at present offer any vast opening for special branches of British energy, it is at least not a market to be passed by. "These rich regions," says Mr. Cooke, "will be to Russia's mighty millions what our Colonies are to the British Isles. They will harbour her surplus populations. Even now Russian immigrants into Siberia, peasants though they be, are supplying the London market with butter, and as they reap their crops with American harvesters, discuss with intelligence the rival performances of machines from Milwaukee or Chicago."

Mr. Cooke's description of the British position in the commercial rivalry of the nations for Siberian trade is not pleasant reading. It is but natural that Russian firms should start branches in Siberia or found independent enterprises. But foreigners too are active and successful. The Danes and the Americans have worked wonders in two branches of the agricultural conditions of the country. The Germans give proof of their capacity to study and adapt their ways and wares to the customs and requirements of the inhabitants. The Swedes share with the Danes the market for dairy accessories. The French have seized something of the demand for fancy goods and toilet articles, the Belgians for guns, and the Austrians for scythes and sickles. Englishmen maintain their reputation for first-class quality in a variety of goods, and for the high price which precludes their adoption. And the irony of it is that it is Great Britain that for the most part furnishes the funds that enable the Siberian peasants to provide themselves in increasing abundance with separators and dairy appliances from Denmark and Sweden, and with agricultural machinery from the United States. The British manufacturing market supplies nothing, and these two branches of trade afford, in Western Siberia at least, the principal and indeed the sole opportunities that have hitherto arisen for foreign importation of any appreciable extent.

Nothing is more remarkable in the commercial history of the last generation than the growth of the butter-making industry of Western Siberia. It is one of the first results of the construction of the railway, and from the point of view of the general well-being of the peasant population the most promising outcrop of the conditions now prevailing. It is at present the main resource of the inhabitants of the entire region. During the succession of bad harvests previous to last year, which crippled the earnings of the peasants and entailed a general stagnation of business in a country exclusively dependent on the crops as Western Siberia, the income derived from the sale of their milk and butter saved the peasants from much of the suffering and destitution that must otherwise inevitably have befallen them. Previous to 1893 no butter was produced in Siberia for export abroad. The first to make butter under modern

methods in Siberia was an English woman married to a Russian, whose dairy farm at Chernaia Reitchka in the district of Tiumen, was in 1886 the only one in Siberia, and is still a well-known model of its kind. The initial difficulties encountered must have been very depressing. No experienced hands were to be found, the peasants did not understand that cows had to be properly fed or attended to, the distances were enormous, and communications were non-existent or primitive, while the people in general had but faint ideas as to the difference between cheese and butter and how they were to be eaten. In 1893 Mr. Wolkoff, a Russian, opened near Kourgan the first dairy producing butter for export beyond the Urals: 14,400 lbs. were exported in 1894. Ten years later butter-making had become the staple industry of the country as regards international trade, and the chief resource of its peasant population. Over 2,000 dairies are now scattered over Western Siberia, their export in 1903 being 2,185,000 pouds, or 78,904,720 lbs. Butter, thanks solely to the Siberian supply, now occupies the sixth place in value in the Russian export trade, and promises to exceed all other items except grain. The British market is Siberia's largest customer, Denmark acting as a forwarding agent. In 1899, the import from Russia was so inconsiderable as to be merely included in the Board of Trade returns under "other countries." In 1900, it forced its way to an individual heading, the exports from Russia amounting to 378 452 cwts. Last year, the butter exports from Russia, mostly from Siberia, were valued at about 30,000,000 roubles.

Unfortunately, as Mr. Cooke shows, Great Britain, though the largest producer of the manufactured product, has no share in supplying the dairy accessories in local demand. "The parchment used for packing the casks is Russian, Flemish, or German. The casks are made locally from beach staves, imported mostly from Germany by rail, though also from Denmark. The colours used for colouring the butter the yellow tinge required by the British market are chiefly Danish, though Russian colours are also in use. . . . The separators are almost entirely Danish, or Swedish, a well-known Stockholm article easily holding the field." Agents of the Stockholm and Copenhagen makers of dairy appurtenances work the country thoroughly, and every butter office is a practical advertisement of their articles. The price lists, catalogues, instructions, illustrated sheet advertisements, and coloured pictorial representations of the machines at work are met with in all directions, and are all in the Russian language, with moneys, measures, weights, dimensions, &c., in equivalents understood by the people.

It is much the same with agricultural machinery. Here the Americans have made the market their own. The vast expanses of their own continent, and somewhat similar conditions of cultivation, give them an advantage in competition with other nations. The distinguishing characteristics of the machines are lightness, simplicity, and ease of use, while stress of competition has reduced prices to the means of the peasant cultivator. Mr. Cooke says that the almost universal monopoly acquired by the United States is shown on interviewing the owners or managers, examining their stores, or studying their catalogues. "Russian and American," not "Russian and Foreign," machines are everywhere advertised. American machines are at almost every depot, Russian manufacturers, at their own establishments, exhibiting them alongside their own similar articles. What competition there is bears an inter-American rather than an international character, New York, Chicago, Auburn, Milwaukee, and other contending centres of manufacture disputing the field. "This new and promising market," says Mr. Cooke, "has been conquered by a careful study of the requirements and peculiarities of Siberian climatic and trading conditions generally, and especially of the demands, preferences, and prejudices of the peasant, who is the sole buyer. The machine is made for the man, and not the man for the machine." It is worthy of note that, including the extreme Far Eastern ports, there is no American official of any kind in the length and breadth of Siberia.

In Siberia proper, Germany has the larger share of the general machinery market, apart from agricultural, though it is rivalled by the United States and Great Britain in Far Eastern ports. The chief causes of German predominance would seem to be (1) superior cheapness, (2) lightness and general correspondence of goods to requirements, (3) greater pushing of goods and willingness to accept business however small as well as to meet all possible suggestions and adaptations, (4) the presence of German resident firms or business men at the bigger centres and periodical visits of representatives, (5) the greater currency of the German language in business circles, the practical nature of their catalogues, price lists, and terms, the facilities they proffer, the initial risks they are willing to run in order to start business, and in general their undoubtedly superior knowledge of the country and its business customs and ways.

Mr. Cooke's explanation of the failure of British traders to get any considerable portion of the Siberian trade has little that is novel in it. British goods are not pushed, or the requirements of the market studied. "Much is lost by not pushing English goods. They have to be sought even when they are heard of at all. British articles are neither accessible nor forthcoming, and in Siberia it is the article on the spot that is bought. British catalogues are not drawn up for Siberian customers, but such as appear in Siberia are looked upon as undecipherable puzzles. Among other things, the exact weight, gross and net, so important for calculating duty and freight, is seldom given, or is given in intricate figures and measures. It is a trite subject, but I can but repeat what I have heard everywhere. 'The English are too proud,' was a favourite expression of opinion, though German

rivals in some centres employed another term, implying inaction. It is only natural, however, from the very nature of the country, its distances, and its population, that the articles which sell are those that are brought there, and not those that have to be first heard of, and then sought out and ordered through second or third hands." Add that in a country where all trade is on a credit basis the British trader requires cash and eschews cheapness, and it is not surprising that British exports to Siberia remain comparatively insignificant. "Sure, solid, and select," says Mr. Cooke, "would seem to characterise British business activity, but the range thus covered is a circumscribed one."

THE AUSTRALIAN MEAT TRADE.*

Within the last few years beef and mutton have become staple articles of Australian export, yet it is not so very long ago when such a result was deemed impossible, at any rate so far as shipments of fresh meat were concerned. For a considerable period the over-sea consignments consisted of tinned meats, for which there would have been a larger demand had the tins presented a more attractive appearance and been of smaller size. With the establishment of regular and speedy steam communication between Europe and Australia, accompanied by the necessary provision of cold-storage accommodation, the Australian meat export trade became rapidly developed. the quantity shipped in 1903 being 102,925,879 lbs., value £1,402,993. Two years previously, in 1901, the quantity was 189,263,239 lbs., value 1,989,455, the drought being responsible for the shortage in 1903, which is disappearing during the present year. The whole of the shipments are made from Victoria, New South Wales, South Australia, and Queensland, the latter State furnishing most of the beef, which is of first-class quality, by reason of the abundance of rich pasturage available. In 1903-4, there were 2,481,717 head of cattle in Queensland, against 4,622,978 head in the other States. There are extensive areas of luxuriant grazing country in the Kimberley district in Western Australia, also in the northern territory, but in the latter the rapidity with which the ground becomes covered with dense scrub constitutes a source of difficulty. In the number of sheep New South Wales leads the way with 28,656,501, Victoria following with 8,774,731, Queensland with 8,392,044, South Australia with 5,350,258, Western Australia with 2,600,633, and Tasmanian with 1,597,053 forming a total of 55,371,220. In 1891 the number was 106,421,168, the decrease being a result of the great drought, which was not, however, an unmitigated calamity, because when the number of sheep is unduly large the quality of both meat and wool must necessarily be inferior. With fewer sheep and abundance of feed the conditions become reversed. At the present time the great object of Australian pastoralists is to secure quality in preference to quantity. In 1904-5 there was a considerable increase in the number of sheep, and it is anticipated that within the next few years the figures of 1891 will be approached, unless pastoralists, profiting by the experiences of recent years, refrain from overstocking. The importance of the pastoral industry is recognised in all the States, and in New South Wales the land laws are being amended with a view to stimulating pastoral as well as agricultural production. The work of meat slaughtering and preserving is conducted on an extensive scale. In New South Wales the capacity of the boiling-down works is stated at 633,900 head of cattle, or 16,965,000 sheep; of chilling works, 488,500 head of cattle, or 5,422,800 sheep; of freezing works, 75,500 head of cattle, or 3,150,000 sheep; and of preserving works, 183,000 head of cattle, or 5,545,000 sheep; representing a total of 1,400,900 head of cattle, or 29,982,800 sheep. The number of carcases treated in refrigerating works during 1903 was 3,666 cattle and 299,131 sheep; and in meat preserving works 7,794 cattle and 188,248 sheep. In Queensland there were 16 boiling down, freezing and other works, in which, during 1903, 922 cattle and 110 sheep were boiled down; 108,343 cattle and 102,007 sheep killed for freezing; and 16,409 cattle and 13,309 sheep killed for preserving; the total output being 66,483,364 lbs. frozen beef, 4,906,991 lbs. frozen mutton, 9,773,112 lbs. preserved beef, and 498,416 lbs. preserved mutton. In Victoria there were 14 freezing, &c., establishments, the united output in 1903 including 294,906 frozen sheep, 7,237 cwt. frozen mutton, 1,424 frozen cattle, and 7,237 cwt. preserved mutton. The meats are exported in four different forms—fresh, frozen, chilled, and smoked. The trade in fresh meat is almost wholly inter-State. Respecting the relative merits of chilled and frozen meats, there exists considerable difference of opinion, but, as a matter of fact, frozen meat constitutes the bulk of the over-sea exports, chiefly to Europe and South Africa, being greatly appreciated in the latter country, where it commands a ready sale in preference to that from elsewhere. The exports of Australian preserved meats in 1903 totalled 11,009,277 lbs., value £108,802. Considerable quantities of salted meats are also exported, chiefly to South Africa and the Philippines. There is likewise a large and increasing trade in rabbits, hares, &c., the quantities exported in 1903 being—New South Wales, 787,574 pairs; South Australia, 119,362 pairs; Victoria, 3,501,511 pairs. In 1904, the Victorian exports were about the same as in 1903. It is officially stated that the rabbits are steadily increasing in numbers in Queensland, New South Wales, and Victoria, and in the two former States they constitute a prolific source of difficulty to pastoralists. Their fecundity is truly remarkable.

* Communicated by Mr. John Plummer, Sydney, New South Wales.

A single pair of rabbits, if left undisturbed, will, all things being favourable, have augmented their numbers to four and a half millions in four years.

TRADE OF JAPAN.

The report on the trade of Japan for the year 1904, just issued by the Foreign Office, and prepared by Mr. G. Barclay, Secretary to His Majesty's Legation at Tokio (No. 3,377, Annual Series), shows that, thanks to the long period of cautious trading which followed the economic crisis of 1899-1900, Japan's trade was in a thoroughly healthy condition when war broke out, and since then it has suffered comparatively little. Not only has Japan been in almost uninterrupted possession of the command of the neighbouring seas so that her foreign trade has not suffered serious inconvenience from the enemy's cruisers, her crops last year were very abundant, the yield of rice and silk being higher than ever before. Owing to these circumstances Japan has hitherto borne the strain of the war with remarkable ease. Her foreign trade has reached a level not only in imports but also in exports considerably higher than that of any previous year. Particular industries have suffered, notably the silk manufactures for the home market, and the smaller manufacturers and traders have many of them felt the pinch of restricted credit, but the year has passed without any failures of importance. On the other hand many industries, particularly farming and silk manufactures for the foreign market, as well as those industries which have helped to supply the war's requirements, have enjoyed a period of great prosperity. It has been the policy of the Government, says Mr. Barclay, to purchase as much as possible in Japan—it has been asserted that 70 per cent. of the war expenditure has been spent at home—and there are many examples of struggling industries which have been built up into successful concerns by the large demands on their capacity.

Mr. Barclay thinks it reasonable to assume that the payment of the successive instalments of the domestic loans already floated, amounting to £28,570,000, and the additional taxation imposed by the Diet, will suffice to prevent any serious inflation of the currency. The additional taxation amounts to some £7,500,000 for the year 1905-6, bringing the total increase in the people's burdens from the beginning of the war to nearly £14,000,000, or something like 81 per cent. of the total revenue from taxation in 1903-04. How far the country's general industries will be able to bear these increased taxes, of which one is an import duty of 15 per cent. *ad valorem* on rice, remains to be seen, but the ease with which the domestic loans have been taken up, and the fact that the deposits in the leading banks and the Post Office banks show material progress for the year are hopeful symptoms. The following table shows the deposits at the end of 1904 as compared with December, 1903:—

Deposits in the	Amount. December, 1904.	Amount. December, 1903.
	£	£
Bank of Japan	1,268,000	400,000
Tokio Associated Banks	15,830,000	14,456,000
Post Office Savings' Bank	3,891,000	3,191,000

It will be seen from the following table, compiled by Mr. Barclay from the Finance Department's Monthly Customs Returns, that, as compared with 1903, the increase in the total volume of Japan's foreign trade, as recorded in the Customs, amounted during the past year to £8,566,159, or nearly 14 per cent. Imports increased in value by over £5,500,000, or 17 per cent., and exports by over £3,000,000, or 10 per cent.:—

Years.	Value. Imports.	Value. Exports.	Value. Total.
	£	£	£
1904	37,902,567	32,591,216	70,493,783
1903	32,374,250	29,553,374	61,927,624
1902	27,739,232	26,368,320	54,107,552

Briefly speaking, it may be said that the imports which show declines, and the exports which show most progress, were manufactured or partly-wrought products—a very satisfactory indication of the development of the native industries.

The following table shows approximately the gold reserve and note issue of the Bank of Japan at the close of 1904, and the two preceding years:—

Years.	Gold Reserve.	Note Issue.
	£	£
1904	8,525,000	29,200,000
1903	11,930,000	23,750,000
1902	11,010,000	23,540,000

The value of imports from the British Empire was 24 per cent. higher in 1904 than in the previous year, its share in Japan's Customs amounting to 41 per cent. of the whole, as against 39 per cent. in 1903. The Empire still maintains the second place as a customer of Japan, though her share in the total exports has fallen from 23 to 21 per cent. Having regard to the United Kingdom's position as the principal source of supply for ships, for steam coal, and for certain classes of textiles, needed for army purposes, it is not surprising that, in 1904, she should have had a much larger share in Japan's custom than in ordinary years, and, in effect, Japan has taken from her 54 per cent. more than in 1903, the value of the increase being £2,681,000, or 48 per cent. of the total increase in Japan's imports. With 20 per cent. of the total imports the United Kingdom has resumed her place at the head of the list which she had always held until India passed her in 1903. The strengthening effect which the demand created by the war has had upon certain branches of Japanese industry applies with special force to the workers in cotton mills. For these 1904 was so prosperous that several of them have planned important additions to their establishments. Six of them have set up 1,800 new power looms, an addition of nearly 50 per cent. to their present plant. It is very possible, Mr. Barclay thinks, that for some

time to come the imports of fancy textiles will not be materially affected, "but in the cheaper cottons and woollens British manufacturers must be prepared not only for the loss of the Japanese market, but also, what is more important, for keen Japanese competition in China." The figures for the year indicating, as they do, increased imports into this country of certain lines of textiles which Japan is well able to produce in sufficient quantities for normal use herself, must not be taken as any guide for the future. 1894 saw no interruption in the constant decline in the foreign yarn trade, which has marked recent years. There has been practically no demand for this British staple, except for 16's and 24's, which are used for special purposes, and the value of the trade, which a few years ago used to average close on £1,000,000, has now fallen to £35,000.

The figures for machinery and engines are fairly satisfactory in 1904 as compared with 1903, but less so if the comparison is for a longer period, as will be seen from the following table:—

Values.

Year.	United Kingdom.	United States.	Germany.
	£	£	£
1901	659,000	288,000	187,000
1902	335,000	285,000	112,000
1903	415,000	294,000	82,000
1904	492,000	371,000	115,000

The Americans are able to deliver quicker, partly because of larger capacity and partly because many standard machines are kept in stock, and they possess a great advantage by reason of their supremacy in electrical machinery. In some branches, such as textile machinery and heavy machinery, the United Kingdom maintains its pre-eminence, but in the great variety of smaller machines both the United States and Germany are competing strongly. Mr. Barclay points out that not only in machinery but in many other articles, the buyer of American goods is better able to estimate ultimate cost than in the case of British manufactures. "The American maker generally issues priced catatogues, and will state discount in an accompanying letter; his prices are usually for machines packed and delivered on the cars. The American railway company taking charge of the goods will quote a through rate of freight per 100 lbs. from the factory to the port of destination." Given an American catalogue with the discounts, the weights of the machine, and the through rate of profit, it is an easy matter to estimate the laid-down cost. Many British manufacturers will not quote discounts except against specific enquiries. Packing is often an unknown extra. So are the rail and steamship charges. As a result the resident merchant finds it difficult to quote prices without a reference home, and thus many an order finds its way to America because the total cost can easily be reckoned, and a price quoted without delay.

Of the tonnage crossing the Pacific between Japan and North America in 1904, 41 per cent. was under the British flag, but Mr. Barclay shows that these figures do not fairly represent the situation. The only wholly British line on the trans-Pacific trade having regular sailings is the Canadian Pacific, with an average tonnage despatched last year from Yokohama to Vancouver of 65,862 tons, or 15 per cent. of the total. The 20 British sailings from San Francisco and Portland, aggregating 48,893 tons, were under charter to American trans-continental railways, and of the steamers under the British flag which left at irregular intervals for Tacoma, Victoria, and Paget Sound, 12 in all, aggregating 54,097 tons, the majority took cargo from Japan engaged for them by the Japanese steamship companies, whose steamers, in consequence of the war, had been temporarily withdrawn from the Pacific. German shipping, with 15 per cent. of the total foreign tonnage, shows an increase of 24 per cent. The establishment by the North German Lloyd of a service between Australia and Yokohama, calling at the German New Guinea ports, deserves special mention.

CARE OF THE AGED IN BELGIUM.

Under the law of May 10th, 1900, it was provided that a pension of 65 francs (£2 12s.) should be granted to every Belgian workman being in a state of need, and having his residence in Belgium, who had reached the age of 65 on January 1st, 1901. Workmen who were at least 55 years of age on January 1st, 1901, were to be allowed the same privileges when they reached the age of 65, but those under the age of 58, at the same date, were excluded from the benefit of the grant, if for a period of at least three years they should not have made deposits with the Government annuity fund of at least 4s. 9d. a year, forming a total of 14s. 3d. The qualifications for receiving the annual pension of £2 12s., are as follows, according to a recent report by the United States Consul-General at Antwerp:—(1) The pensioner must be a Belgian subject; (2) must reside in Belgium; (3) must be at least 65 years old; (4) must be, or have been, a labourer; (5) must be in want. Labourers, for the purposes of this Act, are defined as men and women who work for wages with their hands, for a master, and are paid for their time, or by the piece; and who work on the premises of the master or at home. No distinction is made between the domestic servant, the farm labourer, and the factory hand. Those whose past life corresponds with the above definition, are considered ex-workmen. The wife or the widow of a labourer or ex-labourer is, for the purposes of this Act, also considered a labourer. Those are considered to be in need, for the purposes of this Act whose resources are insufficient to meet their obligations without assistance, and to establish this qualification the following circumstances are taken into consideration. (1) The wages of the interested

person, of his wife, and of his children, and his relatives living with him; (2) the value of their personal property and of the premises which they rent; (3) the nature of their savings, if any; (4) the amount of public charity received, &c.; (5) the cost of house-keeping compared with that of the other labourers in the same trade and in the same neighbourhood, taking into consideration the number and age of those who compose the family; the care of the infirm and sick; (7) rent, taxes, &c.

All foreigners, no matter what may be the legislation of their country, or the length of their residence in Belgium, are excluded from the benefits of this law, unless they have become naturalised. However, a foreign woman who marries a Belgian, becomes a Belgian subject and remains such even after the death of her husband, so long as she resides in Belgium. All who solicit the old-age pension must make their request in writing to the burgomaster of their city, town or village before January 1st of the year during which the pension is to begin. The application must give the name, age, nationality, profession, and residence of the person, as well as a full description of his financial circumstances. The burgomaster will then refer the application to what is known as the committee of patronage, a local body which has under its supervision all matters relating to workmen's dwellings and charitable institutions. It is the committee of patronage which decides upon the merits of all applications and which advises the applicant and the governor of the province of its decisions. From the finding of the committee there is an appeal to the governor of the province. The final decisions are transmitted by the governor to the Minister of Industry and Labour at Brussels, and the Bureau of Labour orders the payment which is made in two instalments of £1 6s. through the local post offices, where the beneficiaries must appear in person and sign their receipts. The Department of Commerce and Labour sends to the Burgomasters during the month of January of each year a list of the persons residing in their districts who receive the pension. The burgomaster notes on his list all deaths, and changes of residence, and any change in the financial circumstances of a pensioner which may have taken place. If the condition of a pensioner is found to have improved during the year, and he is able to maintain himself, the pension ceases. This pension of £2 12s. per annum does not prevent the pensioner from receiving further relief from the board of public charity. No person of the age of 65 may be considered in want whose revenue for his own use amounts to £14 per annum, and no married couple of the age of 65 can be considered in want and receive benefits under this Act whose joint income amounts to £24 per annum. *Employés* of the State, especially postmen, rural police, &c., who are pensioned by the State treasury cannot be considered as labourers under this Act, but those having been employed by the Government railway may be so considered. The number of old age pensioners now on the list and receiving aid from the Belgian Government is something over 200,000.

CONSUMPTION OF HORSEFLESH IN GERMANY.

The increasing consumption of horseflesh among a large class of people of moderate means in Germany, many of whom eat fresh meat of any kind only on Sundays and holidays, has been specially remarked upon. There is in the Greifswalder Strasse, Berlin, a regularly installed horse slaughterhouse, which is under careful police supervision with a veterinary surgeon in attendance to see that no animal is killed, the flesh of which, by reason of disease or other cause, would be unfit for human food. In 1895 the whole number of horses killed in Berlin for human consumption was 7,267. In 1900 the number had increased to 10,815, and in 1904 to about 13,000. Estimating that an average sized horse will yield 230 pounds of edible flesh there was derived from this source last year about 2,990,000 pounds of meat, which was sold for consumption in 64 shops which are specially licensed for that purpose. The United States Consul-General says that at Breslau, which has a population of about 500,000 against 2,500,000 in Berlin and its suburbs, 3,800 horses were killed last year for human food, so that the proportion of horseflesh eaten per capita was much larger in Breslau than in Berlin. In southern Germany and notably in Saxony, where the percentage of working people in manufacturing districts is exceptionally large, the consumption of horseflesh is still greater, and is constantly increasing. The choicest cuts of horse meat sell in Berlin from fourpence to fivepence per pound. Meat from the forequarters or from any part of poor, old, or inferior horses sell as low as three halfpence and twopence. The liver, however, is considered a delicate morsel, and fetches fivepence a pound. The inferior pieces go into the mill for the manufacture of those strongly-spiced sausages flavoured with garlic that are the favourite food of many of the poorer classes in Germany. In the better grade of these sausages pork is mixed, to give the requisite fatness, and when sold for consumption in Berlin they must be plainly labelled "Pferdefleisch" (horseflesh). Outside the municipality this regulation is, however, not enforced, so that quantities of sausages made of horseflesh, with only a small per-centage of pork, veal, or other meat in their composition, are sold to the country districts or exported to the neighbouring countries as ordinary pork sausages. The American Consul adds that, apart from the very general sentiment of respect for the horse as an animal too noble and useful for the degradation of the slaughterhouse, there is perhaps no good reason why its flesh is not as clean and nutritious as that of horned cattle, and the fact of its far greater cheapness in a country where all meat is

so costly as it is in Germany, makes the well-regulated system of horseflesh preparation and supply in Berlin a real boon to a large class of people.

GENERAL NOTES.

IMPROVEMENTS IN THE INDIAN INDIGO INDUSTRY. — At Dalsingh Serai laboratory some experiments have been carried on by Messrs. Bloxam, Leake and Finlow, the report of which has been published. Unfortunately, great difficulties had to be overcome owing to the unfurnished state and limited accommodation of the laboratory, but the results are said to give promise of greater success in the future. Messrs. Bloxham and Finlow have discovered a method of isolating pure indigotin both cheaply and in large quantities from the crude material, so much so that it is proposed to work it commercially, although the efficiency of the process is not yet exactly determined. More important still, is the aid this discovery will possibly lend to further investigation of the indigo industry. The red colouring matter was also analysed, with a result that much of it was found to be present in both the artificial and plant indigo, but one was, it is thought, not the same as "indirubin." Indigo containing this red is of much higher value than that containing blue colouring matters only. Mr. Leake has tried to improve the indigo by a process of selection and has succeeded in so far as in certain experimental plots at Dalsingh Serai, the produce is as much as doubled since 1903. These laboratories are now under the Pusa Institute, and are used for the furtherance of everything affecting agriculture by original research. The results obtained under the old *régime* are favourable in themselves, but still greater successes may be expected when the Government undertake the work, and when the experimenters are not hampered by lack of means or accommodation.

MOTOR BOATS AND HERRING FISHING.—The question of auxiliary power to sailing vessels has become one of increasing importance. In the Shetland Islands, says Mr. Consul Villiers, in his report on the Faroe Islands for 1904 (No. 3404, Annual Series), it has been declared vitally important for the herring fishing. A benzine motor boat has been plying among the islands for some time, but petroleum motors are now chiefly attracting public attention. More than one fishing smack has already been satisfactorily supplied with a petroleum motor, giving a speed of six or seven knots. The first was a vessel of about 50 tons. Smacks are thus enabled to enter harbours promptly with their catch, and leave again at will for the fishing banks, without waiting for the chance of a favourable breeze and not too strong a current. A telegraphic cable is about to be laid from the Shetland Islands to Faroe and Iceland, and will be open for public service on October 1, 1906. Telegraphic communication will be of much service to British fishing companies since it is very important to them that their vessels should not be entirely isolated, especially in case of wreck or break-down, and the cable must materially assist in the development of the growing fishing industry. Prices will be quoted, and vessels will know when and where to sell their fish to the best advantage, instead of sailing vaguely hence as now.

PERSIAN GULF TRADE.—According to the German Consul at Bushire, the imports of Bander Abbas, on the Persian Gulf, in the fiscal year ended March 31, 1904, were valued at £340,000, and the exports were valued at £91,000. The imports consist chiefly of cotton textiles and yarns, sugar, tea, and metal wares, of which £120,000 worth were received from Great Britain, £127,000 worth were from the British East Indies, about £42,000 worth from France, and the remainder was furnished by Austria-Hungary, China, the Dutch Indies, Russia, Belgium, and Japan. Four-fifths of the exports go to British East Indies, and consist mainly of almonds, raisins, wool, opium, and Persian carpets. The trade is in the hands of Persian and Indian firms, and the imported goods go to South-Eastern Persia and Western Afghanistan.

COTTON GROWING IN EAST AFRICA.—The report of Messrs. Linton and Brand on the cultivation of cotton in East Africa does not point to early and extensive development of the industry in those regions. The settler intending to grow cotton cannot do with a smaller capital than £750. He must be able to train his own oxen, and willing to plough and do all other necessary work until natives are trained to it. Labour cannot be said to be dear, varying from 5s. 4d. to 13s. 4d. per mensem, but it is deficient both in quality and quantity. The obvious remedy is to bring tillage implements into more general use, but here two difficulties have to be faced —skilled labour is unobtainable to work the implements, and in certain districts cattle can scarcely exist. And when the master has produced his cotton he finds it difficult to get rid of it. "Just when farmers are beginning, and in most need of all possible facilities, it is unfortunate that no cotton market exists, and that transport, more particularly sea transport, is in an unsatisfactory state." The natives are beginning to grow cotton, but they are apathetic, and require constant supervision. The conclusion arrived at by Messrs. Linton and Brand is that "Until the labour question is solved, it would be dangerous for even the present settlers to count on cultivating more than a few hundred acres each, and, in short, the total area cropped under European supervision can scarcely exceed a few thousand acres."

Journal of the Society of Arts.

No. 2,747. VOL. LIII.

FRIDAY, JULY 14, 1905.

NOTICES.

CHAIRMANSHIP OF COUNCIL.

On Monday, 10th inst., at their first meeting, the Council elected Sir Owen Roberts, M.A., D.C.L., F.S.A., as Chairman for the ensuing year.

The various Committees were re-appointed.

COUNCIL.

At the last meeting of the Council, on Monday, 10th inst., Sir Philip Magnus was elected a Vice-President of the Society, in place of Mr. William Thomas Shaw, who is unable to accept the office.

APPLIED ART SECTION COMMITTEE.

A meeting of the Committee of the Applied Art Section was held on Tuesday afternoon, 11th inst. Present: Sir George Birdwood, K.C.I.E., C.S.I., in the chair, Lewis Foreman Day, F.S.A., Gerald C. Horsley, A. Lasenby Liberty, Halsey Ricardo, and Sir Thomas Wardle, with Sir Henry Trueman Wood, Secretary of the Society, and Henry B. Wheatley, Secretary of the Section.

The arrangements for next session were considered.

INDIAN SECTION COMMITTEE.

A meeting of the Committee of the Indian Section was held on Wednesday afternoon, 12th inst. Present:—Sir William Lee-Warner, K.C.S.I., in the chair, Sir Mancherjee Bhownaggree, K.C.I.E., M.P., Sir George Birdwood, K.C.I.E., C.S.I., F. C. Danvers, General J. Michael, C.S.I., Thomas H. Thornton, C.S.I., D.C.L., Sir Raymond West, K.C.I.E., LL.D., Arthur N. Wollaston, C.I.E., W. Martin Wood, with S. Digby, Secretary of the Section.

PRACTICAL EXAMINATIONS IN MUSIC.

The practical examinations in Music were not concluded this year until the 5th July, too late for the results to be included in the Report of the Council. They lasted for 11 days.

The examination was conducted by Dr. Ernest Walker, M.A., and Mr. Burnham Horner.

The system of examination was the same as that for recent years. For instrumental music certain standards are given, and candidates are asked to select for themselves which of these standards they choose to be examined in. The standards range from easy to very difficult music. For each standard a list of music is given for study, and from this list candidates select the pieces they will sing or play. Candidates are expected to play or sing the pieces which they have prepared, to play or sing a piece, or portion of a piece, at sight, and to play certain scales.

In all, 437 candidates entered, and of these 418 were examined, a decrease of 139 as compared with last year. There were 319 passes and 99 failures.

The following were the subjects taken up:—Piano, singing, violin, violoncello, viola, and clarinet. 343 entered for the piano, 257 of whom passed; 55 entered for the violin, of whom 47 passed; 3 entered for the violoncello, all of whom passed; 14 entered for singing, of whom 9 passed; 2 entered and passed for the viola, and one for the clarinet. No medals were awarded.

The Examiners report that the chief causes of failure to secure a certificate were owing to the non-observance of good touch and tone, exaggerated accent, or inability to perform the music at the recognised pace. There were also some cases where the candidate showed inadequate knowledge of the minor scales, whilst others were quite unprepared with them. In several respects, indeed, there was evidence of want of care in reading the printed conditions.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

INTERNAL COMBUSTION ENGINES.

By Dugald Clerk, M.Inst.C.E.

Lecture II.—Delivered February 20th, 1905.

Syllabus.

Indicator Diagrams and Power Tests.—Diagrams from engines using coal gas, producer gas, blast furnace gas, petrol and heavy oils—Practical efficiencies and limitations in large and small motors for constant volume and constant pressure engines—Brake tests—Irregularities in diagrams, pre-ignitions, exhaust explosions, missed ignitions.

In considering the indicator diagrams obtained from actual engines, it is necessary to remember that the operations of the ideal engines which I have briefly discussed in my first lecture, are not followed in many respects. The actual engines differ from the ideal ones in many ways. Following the cycle of operations as it occurs in a constant volume engine:

(1) The working fluid generally gains some heat on entering the cylinder at a time when it would be better for the temperature to remain at its lowest point.

(2) During compression, the line followed is not quite adiabatic. There is a certain amount of heat loss going on to the sides of the cylinder after a certain part of the stroke is completed.

(3) The supply of heat is never added instantaneously as required in this type. Naturally the spread of the flame takes some time, although undoubtedly that time is very short. The time taken, however, depends upon many circumstances, some of which we shall consider.

(4) During the expansion stroke, after heat has been added, considerable heat loss occurs to enclosing walls and to the end of the piston.

(5) The working fluid does not behave as a perfect gas. Owing to the complex phenomena of combustion its physical state is changed to some extent during the addition of heat; that is, while we compress one working fluid, viz., a mixture of inflammable vapour and air, we expand another working fluid, viz., a mixture of nitrogen, some oxygen, and products of combustion.

(6) The admission, transfer and expulsion of the working fluid are not accomplished without some resistance—throttling during admission and back pressure during exhaust.

In discussing the effect of these necessary conditions of the practical engine, I propose to begin with the Otto or four-stroke cycle, following with the Clerk or two-stroke cycle, and concluding with constant pressure cycles, whether using four or two stroke mechanism.

In all these types, I shall follow the charge through the engine, dealing first with the charging stroke and its losses, then the explosion or ignition period, then expansion, and lastly, the exhaust period, discussing as we proceed the precautions necessary to secure the best results.

On the charging stroke the losses are of two kinds, both of which tend to reduce the charge weight admitted to the cylinder. The mechanical loss is due to throttling at admission, and the physical loss is due to heating of the charge as it enters the cylinder. It is the object of the engine designer to get the greatest possible weight of charge into the cylinder per stroke, so as to obtain the maximum power for given dimensions. Throttling during admission causes loss by resistance to the movement of the piston, but this loss is trifling. In a well-designed engine, it does not usually exceed from 1·5 to 2 lbs. per square inch. Such a loss is between 2 per cent. and 3 per cent. of the indicated power, and so far as resistance to engine movement is concerned, slight variations are of little importance. This point, however, requires careful attention for another reason: the effect of throttle on charge weight is very material. Assume atmospheric pressure to be 15 lbs. per square inch, then a deficit of 1·5 lbs. means reduction of charge weight by 10 per cent.; 3 lbs. reduction by 20 per cent. That is, in a given engine with certain permissible limits of maximum temperature, the power would be reduced by 10 per cent. by the first imperfect filling, and 20 per cent. by the second. It is therefore of great importance to secure the proper filling up of the cylinder to atmosphere at the out end of the stroke. This is secured in the best gas engines by holding the inlet valves open considerably after the crank crosses its out centre. In many engines running at fair piston speeds the inlet valve does not completely close till the crank has passed from 30° to 40° under the centre. As the cams of modern engines are all of the trailing type, so as to secure quiet seating, this results in the valve being well open at the end of the stroke, and practically closed before the piston returns materially.

To obtain the best result, it is necessary to keep the charge velocity through the inlet valve low and have the air and gas passages

as direct as possible. A very usual mean charge velocity is 80 feet per second. To secure this free charging, the inlet valve also opens before the termination of the exhaust stroke—30 per cent. is usual—and for another reason the exhaust and charging valves are often open together. The effect of throttling in reducing the power of the engine is the same as that found in engines working up among the mountains. Assuming barometric pressure at the sea level to be 30 inches of mercury, then at 3,000 feet up the pressure would be about 27 inches, so that the engine would lose 10 per cent. of its power. This loss is analogous to loss due to throttle.

So much for the mechanical loss. The heating loss acts in the same direction. Gas engines of moderate dimensions, say up to 18 inches cylinder diameter, are found to give maximum economy when the water jacket is somewhat warm, usually about 80° C. Working in this condition at nearly full load, the piston end gets somewhat hot, something like 400° C. in an engine of small dimensions; and in one so large as 20 inches diameter, something like 700° C., or a dull red in the dark. I am referring of course to ordinary pistons without water jacketing in the piston itself. The exhaust valve also heats to about 400°. When the charge, therefore, enters the cylinder the air and gas supply being at a temperature of, say, 17° C., it comes in contact with walls heated to 80° C., and a piston end and exhaust valve much hotter. This raises the temperature of the charge as it enters, so that when the cylinder is completely charged it is considerably hotter. It is difficult to determine this temperature, but it is very important to know it, not only from the point of view of loss of power, but also from that of pre-ignition. A comparatively small rise in charging temperature will readily produce dangerous pre-ignitions in large engines, and annoying ones in small. Measuring this charge temperature as best one can, it is found that 100° C. is not uncommon. Now a rise from 17° C. to 100° C. reduces the charge weight, and therefore the engine power, from 1·0 to 0·775; that is, it reduces the power by 22·5 per cent. Thus we see that for every degree Centigrade rise above 17° C., we lose power in the engine by 0·344 per cent.

From the point of view of power alone, it is accordingly very important to keep down the charge temperature, as a loss of 20 per cent. and more is easily incurred in this way. So far, the moral of all this is, if the maximum power is required from the engine, keep everything as cool as possible.

The cylinder has now been charged, and the piston is ready to compress the charge into the combustion space; and here new conditions arise. To get adiabatic compression, there should be the least possible temperature difference between the enclosed charge and the walls. Compressing in a very usual ratio to $\frac{1}{5}$ volume, as shown in several of these diagrams, the temperature would rise from 17° C.—without heat losses to about 300° C. The mean temperature of the walls is, of course, lower than this, so on the compression stroke heat losses occur. These would not be serious if the initial temperature had really been 17° C.; but with initial temperature of 100° C. the terminal temperature of adiabatic compression is very much greater; it would rise as high as 470° C. In this case, therefore, there is some loss to the walls. To minimise loss the walls should have approached the temperature more nearly, but that, of course, is impossible, and in this part of the process also the least loss would be found in keeping down wall temperature. Compression being completed, the inflammable mixture is ignited. The time of firing varies with the nature of the gas used; but the object is to make the heat addition as quickly as possible, without causing the pressure to rise so quickly as to produce shock in the engine. With a weak mixture the ignition must be begun early, while the crank is well under the centre, so as to complete the inflammation before the piston has time to make much forward movement. As a rule maximum temperature should be attained before the piston has performed more than $\frac{1}{70}$th of its forward stroke, otherwise the good effect of high compression is to some extent lost. It does not do to ignite too early, however, even to get maximum temperature at the very end of the stroke, as then the hottest flame is exposed for so long a period that the expansion curve falls to a lower point than would otherwise be the case.

The piston now proceeds on the expansion stroke, and the study of the expansion line is of great interest. It is generally stated that this expansion line follows a curve which can be expressed by the equation

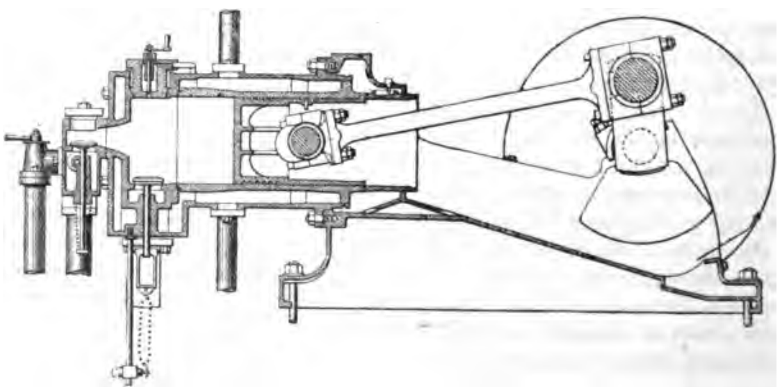
$$PV^k = \text{const.}$$

A close investigation of many of these curves, however, shows that this is by no means uniformly true. The expansion curve is in part

isothermal, and part no doubt can be expressed in this way; but different parts have varying values of *k*. It is very important to study this curve thoroughly. To do this, it is desirable to follow the temperature from point to point. To do this easily, I find it a good way to draw an isothermal line from the out end of the stroke, and then to measure the different temperatures in terms of the pressure values on that line, keeping in mind that at every point of the curve temperature is proportional to absolute pressure. When investigating a number of cards, it is convenient to have isothermal temperature scales made so as to read off temperature at each point of the diagram directly.

The interest of this expansion lies in the fact that further advance is to be found in but a variable specific heat does do this. And no doubt it is true that there is some variation of specific heat in the case of high temperature flames, such as those of the gaseous or vapour explosion. Carbonic acid gas cannot be far from its dissociating point, and no doubt specific heat increases to some extent because of that. This appears to be proved by Professor Harold Dixon's experiments. Steam also may be near its dissociation point, although not so near as CO_2. This, however, by no means accounts for all the phenomena of heat suppression, because at low temperatures there is as great a heat suppression as at high; and this of course could not be so if increasing specific heat furnished the whole explanation. All are agreed on two things, then: that heat is

FIG. 10.



VERTICAL SECTION OF NATIONAL GAS ENGINE.
Type "X." Diameter of cylinder 14"; stroke 22"; B.H.P. 68.

understanding its message fully; and a very difficult study we find it. One fact, however, emerges clearly: that is, heat is added during the expansion stroke. On this the rival theories are at one. It does not matter whether we adopt the varying specific heat theory, or continued combustion theory, both agree that heat is added. I have observed that many engineers imagine that increasing specific heat at high temperatures does away with the idea of heat additions, because the expanding line becomes an adiabatic, with varying specific heat. But the idea of an adiabatic line with varying specific heat is only another way of saying that the gas is not a perfect gas, but is a substance capable of rendering heat latent, and giving it up again, just like the case of water and steam. A higher constant specific heat does not imply the idea of heat evolution, or absorption; added in the expansion curve, as well as on the rising temperature curve. They differ on the explanation, but all admit the fact.

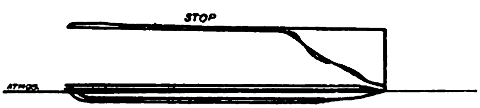
The cycle is completed by the opening of the exhaust valve, and the expulsion of the products of combustion. This should of course be done with as little resistance as possible. Mean velocity of exhaust in a good engine will be about 70 feet per second. To furnish the data required for the careful study of a diagram, it is necessary to determine the following principal quantities, in addition to taking diagrams:—Brake power, indicated power, gas consumption, air consumption, heat flow through jacket, radiation from engine, heat carried away by exhaust gases, heat value of gas, engine dimensions, clearance space.

I will now consider diagrams taken by myself in tests recently made with a National

gas engine, called by the National Company "X" type, having a cylinder diameter of 14 inches, and a stroke of 22 inches. The engine is shown in the section, Fig. 10. I have taken this engine for the purpose of explanation, because the clearance spaces have been accurately determined, and all the dimensions of the engine and particulars are fully before me. In many cases it is impossible to extract all the information which diagrams can give for lack of knowledge of such data as clearance space, and probable temperature of engine jacket.

Fig. 11 is a light spring card from the

FIG. 11.



LIGHT SPRING CARD FROM NATIONAL GAS ENGINE.

engine, to show the resistance to charge and discharge. In all engine tests, these light spring cards are taken with a spring having a strength of about 10 lbs. to the inch upon the diagram. They are necessary, as it is otherwise impossible to distinguish clearly what is going on when a heavy spring is in the indicator for the purpose of taking explosion and expansion pressures. From this diagram you will see that the piston on its forward stroke draws in a charge which reduces the pressure to about 1½ lbs. below atmosphere. This is a resistance. At the end of a stroke the cylinder fills up while the piston is crossing the centre, and the cylinder is thus nearly fully charged with a mixture of gas and air. This filling up of the cylinder is very important, as a very small defect of pressure at the charging end of the stroke greatly reduces the power of the engine. All the good engine designers hold open the charging valve while the crank is crossing the centre at the out end of the stroke, so as to enable the pressure to rise as nearly as possible to atmosphere before compression begins. It is accordingly very important, when inspecting a light spring card, to note whether the cylinder is well filled or not. The object of the designer is to cause the cylinder to fill entirely up to atmospheric pressure before the piston returns on its compressing stroke. The light spring card also shows a line above the atmospheric line, the higher pressure being due to the resistance of the exhaust gases. The mean back pressure from this cause is something like 2 lbs. on the square inch. It is an interesting fact that when an engine is governing in the commonest English method—that is, by cutting out impulses—the discharge stroke of the cold air always shows a greater back pressure than that of the hot exhaust. This is due in part to the heavier weight which must be moved by the piston, when the gas to be discharged is cold, and in part to the fact that a vacuum wave is caused in the exhaust pipe of a gas engine by the act of discharging the exhaust from a pressure above atmosphere. So far as the light spring card is concerned, the two main points to be noted are the resistance on the suction stroke, and the terminal pressure before compression. Further, the freedom of the exhaust discharge is also to be noted, although that may vary to a greater extent than the charging resistance, without causing serious loss in the operation of the engine. So much for the light spring card.

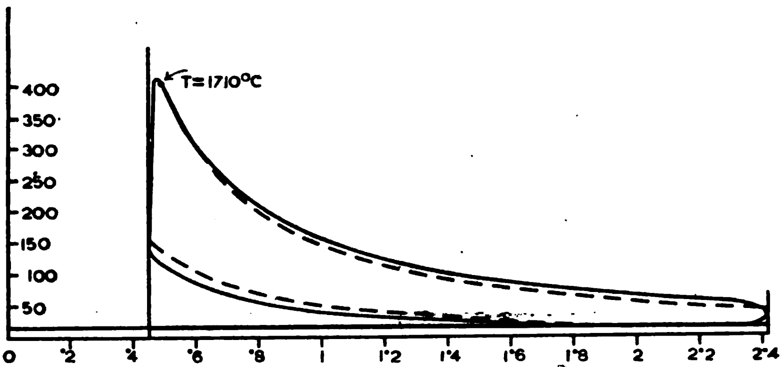
Fig. 12 shows an indicator card taken with a heavy spring. In it is seen a slightly thickened line, about the atmospheric line. This is all that is shown of the suction and exhaust resistance, because of the very powerful spring necessary to resist the explosion pressure. This card is used to follow the compression, the ignition, the expansion, and the first part of the exhaust—that which falls from the terminal expansion pressure to the atmosphere.

Looking at this card, in the light of experience of many diagrams, it becomes obvious that the mixture here has been slightly too strong. The result is distinctly economical, but it is not so economical as the result with a slightly weaker charge. I have marked under the diagram the various particulars of the test made at the time at which the diagram was taken. Upon this diagram I have shown the clearance space of the engine, and I have calculated and plotted upon the diagram the adiabatic expansion line from the point of minimum temperature. I have also dotted above the main compression line the adiabatic line which would be followed if no heat loss occurred during compression. From these dotted lines you will see that whereas the compression line falls slightly under the adiabatic the expansion line keeps somewhat above it.

Taking this card, and calculating the heat evolved, the heat accounted for at the point of maximum temperature, I find that altogether some 70 per cent. of the total heat of com-

bustion appears to have been evolved at that point; or, putting it in accordance with the idea of the French physicists, the specific heat of the charge has increased at the high temperatures, and so, although the whole heat is evolved, it cannot produce the effect in increasing the pressure which would be produced had specific heat remained constant. The temperatures at the principal points are given below the diagram; and here it is necessary to explain that some difficulty arises in calculating these temperatures. This difficulty is one which does not depend upon the question of combustion or no combustion, but is a purely experimental one. As you are aware, in order to calculate the temperatures on every already said, is somewhere in the neighbourhood of 80° C., that is, the water jacket, which is seen in Fig. 10, for keeping the cylinder and combustion space cool, is best so arranged that the cylinder is maintained at this temperature. Under these circumstances, in such an engine as this, the piston end of course attains a much higher temperature, and it becomes difficult to estimate what is the exact temperature of the charge as it enters. Assume the air and gas to be entering at atmospheric pressure and temperature, say 17°C., then it is obvious that the charge becomes heated as it passes into the cylinder. The entering gases impinge upon the hot walls upon the hot piston, and so they become heated. They

FIG. 12.



HEAVY SPRING CARD FROM NATIONAL GAS ENGINE.

Rich mixture; mean pressure 94·5 lbs. per sq. in., 57·5 B.H.P.; maximum temperature, 1,710° C.; exhaust temperature, 1,000° C.; temperature of compression, 440° C.; temperature of charge before compression = 90° C.; indicated efficiency, 33 p.c.; dotted lines adiabatics through points of maximum and minimum temperature, $\gamma = 1·408$.

part of this diagram, it is necessary to know the temperature at some one point with some accuracy, or to know the total weight of charge contained within the cylinder just before compression commences. In ordinary tests it is difficult to determine the volume of air taken into the engine, and all that we usually know is the volume of gas used for a given number of strokes, and the volume swept by the piston during its operations. If we knew the weight of charge entering the engine, including the weight of the exhaust gases remaining in the combustion space at the exhaust end of the stroke, then all the temperatures on this diagram could be calculated with ease and certainty.

In the ordinary running of an engine of this type, at anything like full load, it is found that the best water jacket temperature, as I have also become heated to some extent by mixing with the exhaust gases remaining from the previous explosion, in the combustion space of the engine. The question of the heat given by these exhaust gases, and the heat given to the walls, is one which it is necessary to solve in order to know the exact temperature of the incoming charge. In these particular experiments, the air supplying the engine was measured. This determination enables me to give not only the volume of air and gas admitted to the cylinder, but also the volume of air. The only question remaining, therefore, is the weight of the exhaust gas left. This has been determined by several experimenters, and recently the question has been carefully gone into by the Thermodynamic Standard Committee of the Institution of Civil Engineers, of which I have the honour to be a

member. This question has been very carefully considered by that committee, and we hope soon to be able to give some definite results of our labours on this, among many other points. Meantime I may say that the charge temperature on this diagram, determined as nearly as possible, amounts to 90°C. Assuming then this to be the temperature of the charge before compression, the temperature in the different parts of the diagram have been calculated by well-known formulæ. Comparing these figures with those on the ideal card for the same clearance, it appears that the expansion curve shown here is somewhat above the adiabatic. This of course means that in some way heat has been added on the expansion stroke, either by change of specific heat or by continued combustion, so as to make up for the loss passing through the cylinder sides. In this particular test the heat distribution is approximately as follows:—

Indicated work	33·1	57·5 B.H.P.
Jacket loss	36·0	
Radiation	6·0	
Exhaust loss	42·0	
	107·1	

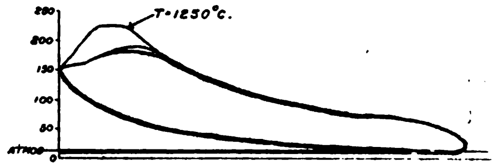
This method of determining the disposition of the heat should always overbalance. The reason for this is that part of the heat set down as exhaust loss does not really get away from the engine. The hot exhaust gases impinge on the surfaces of the valve boxes and exhaust passage, and thus give up part of their heat to the engine and water jacket. This heat is thus taken into account, both under the head of jacket loss and as exhaust loss. Part of the loss set down as exhaust loss is also given back to the engine as heat given to the incoming gases.

Here we have a very good efficiency, 33 per cent. for the indicator and 28 per cent. for the brake; but this is not the best result which the engine can give.

The efficiency may be improved by slightly throttling the gas so as to give a smaller gas supply. The ignition would then take a longer time, and the upper part of the explosion curve on the diagram would be gently rounded, the maximum temperature being considerably and the mean pressure slightly reduced. An indicated efficiency of 35 per cent. may thus be obtained with this engine.

Fig. 13 shows another card, or series of cards, where the dilution has been carried to an extreme. The effect here is to cause the engine to run, not quite but almost as a constant pressure engine. Considerable reductions in maximum temperature and mean pressure, however, are noted; but as you will see, the economy falls off considerably. It is 25 per cent. Bk. E. and 29 per cent. I.E. Here the consumption has risen from the best point, which is slightly less than that shown in Fig. 12, to about 18 cubic feet per B.H.P.

FIG. 13.



HEAVY SPRING CARD FROM NATIONAL GAS ENGINE.

Very weak mixture; maximum temperature 1250° C.; mean pressure 85 lbs. per sq. in.; indicated efficiency 29 per cent.

per hour, and the power has fallen by more than a third, to 38 B.H.P. These diagrams illustrate the range within which economy may be found. The first diagram corresponds to some extent to what in the steam engine would be known as an overload diagram; slightly less gas would give a diagram of maximum economy; and the diagram (Fig. 13) shows a case where the mixture has been purposely over-diluted. Although the ignition is too late, and consequently the cycle becomes rather a constant pressure than a constant volume cycle, yet the absolute heat loss through the sides of the cylinder is considerably reduced, the relative loss remaining about the same.

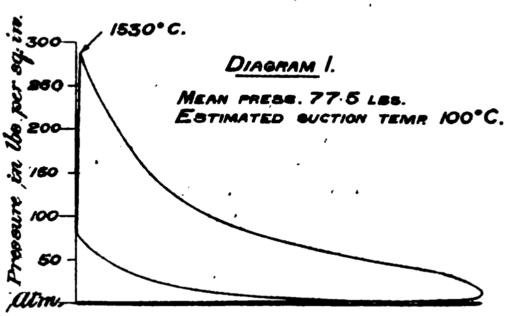
Comparing the efficiencies obtained with a normal gas supply with the standard air engine efficiency given for the same clearance space in the last lecture, you see that the efficiency in the actual cycle ranges from ·6 to ·7 of the ideal. These diagrams are taken with coal gas, and at the time the test was made Junkers's calorimeter was used to determine the heating power of the gas. Measurements have also been taken of air temperature, barometric pressure, and so forth—a sufficient number to give approximately accurate results.

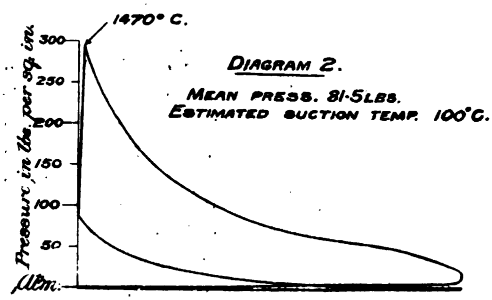
Figs. 14, 15, 16, 17, 18, and 19 show a number of diagrams taken from various engines with different gases,—coal gas, producer gas, blast furnace gas, petrol, and heavy oils. The engines are all standard ones—

Crossley, National, Stockport, Premier, and Richardson Westgarth's Cockerill. I have marked under each diagram the main particulars, so far as I have been able to calculate them from the data furnished to me; and comparing the diagrams you will see that generally the coal gas explosions show fairly sharp rises, as in the Crossley and National engines, while the producer gas explosions generally, though not always, show a gentler rise, and a more indefinite maximum point. Many makers use somewhat higher compressions for producer gas than for coal gas, and when blast furnace gas is used, still higher compressions are adopted. This you can see by looking at Fig. 16, where the compression pressure has risen to nearly 150 lbs. in one case.

The petrol engine diagrams (*see* Fig. 17) were taken by Professor Callender with a very small air-cooled bicycle motor. The revolutions and various particulars are marked under the diagrams.

Fig. 14.





Diagrams 1 and 2 from Crossley Two-cylinder Engine.

Cylinders, $18\frac{1}{2}$ in. diameter by 30 in. stroke; average speed 172 revs. per min.; indicated h.p. 273; brake h.p. 253; indicated thermal efficiency 30·3 per cent.; test made with Manchester Corporation coal gas, 607·5 B.T.U. per cub. ft., lower heat value. Particulars handed to author by W. J. Crossley, Esq.

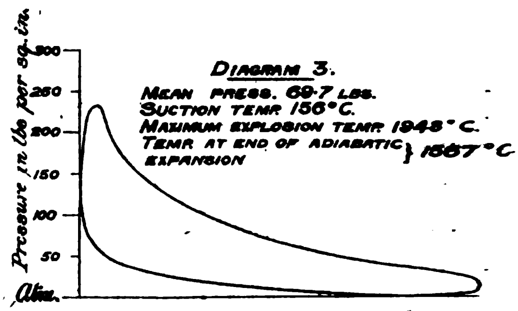


Diagram 3 from Professor Burstall's Second Report to the Inst. M.E.; B trials, Test 1.

Engine cylinder, 6 in. diameter by 12 in. stroke; speed about 200 revs. per min.; indicated thermal efficiency 19 per cent.

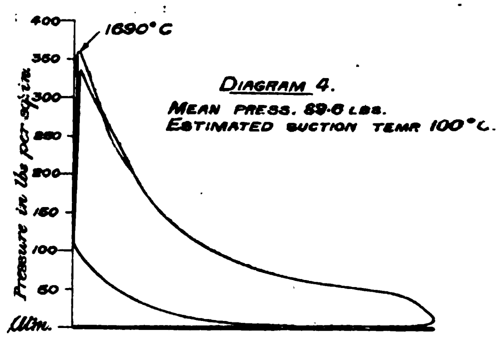

Diagram 4 from National Gas Engine tested by Professor Robinson.

Cylinder, 10 in. diameter by 18 in. stroke; average speed 170·3 revs. per min.; indicated h.p. 26·4; brake h.p. 23; indicated thermal efficiency 28·7 per cent.

Fig. 18 shows diagrams from the well-known Hornsby engine, taken by Professor Robinson; and Fig. 19, similar diagrams from a heavy oil engine by the National Gas Engine Co.

Looking at these diagrams, you will notice that very varying compressions are used, and that the appearance of the diagrams vary to a considerable extent. In all these engines, however, you will find that if the compression space be known, and the efficiency be calculated from the formulæ for constant volume engines using air without heat losses, and that efficiency multiplied by a factor between ·6 and ·7, the practical efficiency of the engine will be at once given.

On the adiabatic compression curve shown in Figs. 5 and 6 I have marked temperature and degrees Centigrade at various stages of compression. A consideration of these temperatures will make evident the reason for

PREMIER GAS ENGINE AT WINNINGTON (TWO CYLINDERS).

Cylinders, 28⅛ in. diameter by 30 in. stroke; air scavenging cylinder, 43¼ in. diameter; average speed, 128 revs. per min.; working with Mond gas; pistons and exhaust valves watered. Diagram taken from engine by Mr. Humphrey in author's presence.

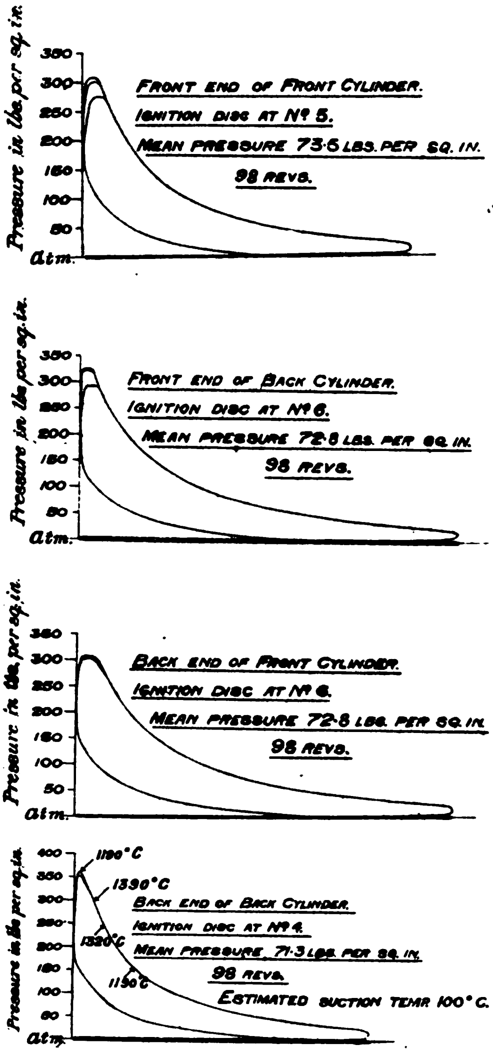
certain limits to increasing efficiency by increasing the compression. Mixtures of inflammable gas and vapour with air ignite at various temperatures, that is, once a certain temperature is exceeded, the mixture ignites. This igniting point is not very well defined, as a very slow combustion appears to take place in dilute mixtures at quite low temperatures. This has been proved by the investigation of both English and Continental chemists.

Many experiments have been made showing that, with certain mixtures of inflammable gases with oxygen or air, exposure may be made to certain temperatures without ignition; but when these temperatures are slightly exceeded the mixtures begin to ignite.

Looking at the adiabatic compression curve shown in Fig. 5 it will be seen that the temperature rises from 17° C., until at the pressure of 500 lbs. per square inch it reaches something like 600° C. This assumes that the charge before compression is at a temperature of 17° C. If, however, as is the case in the gas-engine cylinder, the temperature be nearly 100° C., then the temperature with compression to 500 lbs. is very materially increased. It is increased, in fact, in the ratio between the two initial absolute temperatures. With a Diesel oil engine running at full load, compressing to 500 lbs. on the square inch, the temperature will readily rise to something like 800° C. This is a fair red heat, and this temperature would ignite any inflammable mixture of gas and air.

The problem present to the designer of a constant volume engine is to get as high compression as possible, without exceeding the temperature of ignition of the particular

FIG. 16.



GAS ENGINE (COCHRANE, No. 250).

Cylinders, $29\frac{1}{4}$ in. diameter by $35\frac{1}{2}$ in. stroke; piston rods, $7\frac{2}{5}$ in. diameter; mean M.P. of 4 cards—72·6 lbs.; total I.H.P. at 98 revs.—810; indicator diagrams taken on July 15th, 1904, with temporary load on dynamo. Diagrams handed to author by Mr. Westgarth.

mixture of inflammable gas and vapour to be used in the engine. Although accurate figures have not yet been obtained, yet it is known in a general way that gases which contain a large proportion of hydrogen are ignited at a comparatively low temperature. With such gases it is accordingly necessary to keep down the compression, if premature ignitions or pre-ignitions are to be avoided. In ordinary practice, with coal gas and air, it is found, for example, that it is unsafe greatly to exceed a compression of one-fifth. If this ratio be exceeded, then any trifling circumstance, such as a spongy place in the piston or combustion space surface, or any little projecting part which can become unduly hot, at once causes frequent pre-ignitions. Pre-ignitions, in fact, are the limiting circumstance which prevents the highest compressions being used in motors of this type.

At Fig. 20 I have an indicator card showing a pre-ignition obtained in this engine, due to a spongy part in a tube carrying the indicator. These pre-ignitions, of course, at once reduce the economy of the engine, because they reduce the area of the diagram, and if pre-ignition becomes at all pronounced, the power

FIG. 17.

FIG. 19.

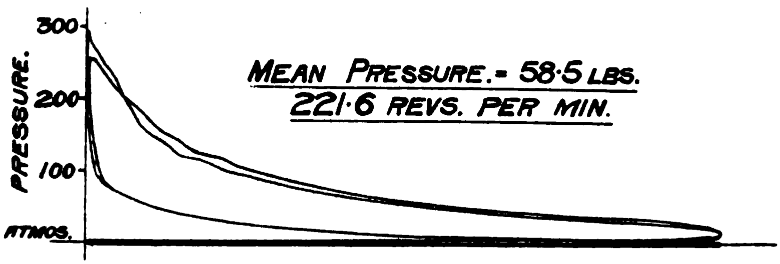

DIAGRAM FROM NATIONAL HEAVY OIL ENGINE. Oil Consumption ·736 lbs. per B.H.P. hour

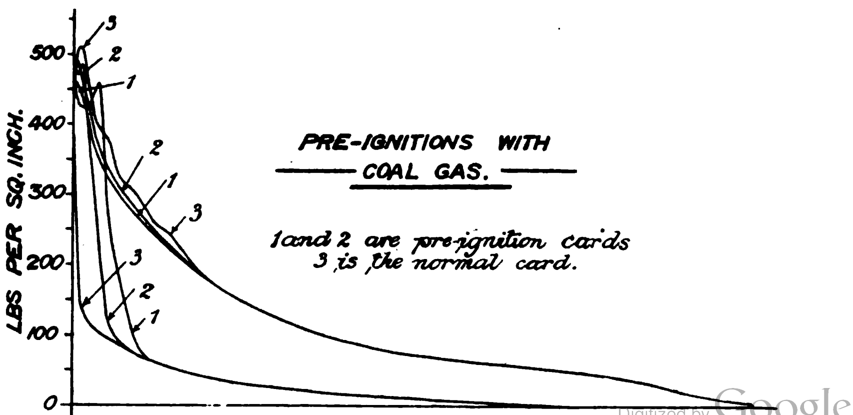
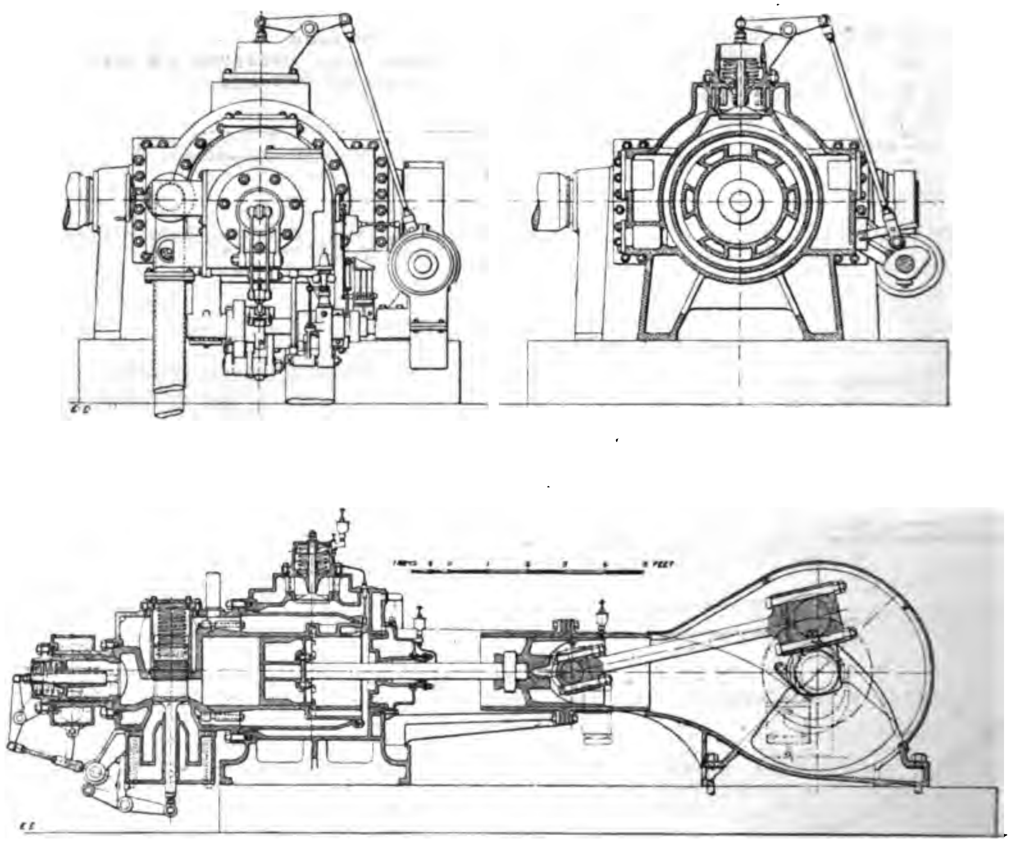
FIG. 20.



falls off with great rapidity. Engines have therefore to be designed to avoid pre-ignition. It has been found, for example, that heavy oil does not stand so much compression as a light oil—that is, a heavy oil, partly because of greater chemical activity, and partly because of the necessity of heating the charge to vaporise it, requires to be operated at lower compression pressure than a gas and air charge, where the charge is relatively cool.

All engineers engaged on gas engine work have to face this difficulty, and various solutions have been advocated. Generally it may be taken that the cooler the incoming charge, the piston, the cylinder, and the combustion chamber can be kept, the less liability is there to pre-ignition. Accordingly, in large gas engines which would otherwise pre-ignite readily, circulating water is very freely used, and the cylinders are kept much cooler than is found to

FIG. 21.



NATIONAL AIR COMPRESSION ENGINE.

give the maximum economy in smaller engines.

This will be seen on looking at the diagrams from the Hornsby and the National heavy oil engines. The great limiting cause in constant volume engines is really the danger of igniting the inflammable charge during the compression stroke; and this trouble becomes more pronounced with large gas engines. On the other hand, most very large gas engines use blast furnace gas, and this gas consists largely of carbonic oxide, with, as a rule, but little hydrogen. Consequently, it can stand a high compression without premature ignition.

In work in which I have recently been engaged at the National Gas Engine Co., I have designed two types of engine which are intended to meet this difficulty. One of these types, the air super-compression engine (shown at Fig. 21); the other, an exhaust super-compression engine, I have no figure here for, as it is still in the experimental stage. By air super-compression and exhaust super-compression, I mean the addition of air or cold exhaust charge under pressure to the engine

charge, and then the compression of the united diluted charge. This addition enables one to get high average pressures with low average temperatures. I have, however, already discussed engines of this type in the James Forrest lecture of last year, and in a paper read before the British Association in August last, so I need not deal with it here. The exhaust and air super-compression seem to me to enable us greatly to improve the performance of these engines by working with a motive fluid which is, on the whole, cooler than that given by an ordinary explosion. In my experiments I work at a maximum temperature of not more than 1,200° C., as against the usual maximum temperature of something like 1,600° C. or 1,700° C. Many engines, however, work at fairly low temperatures, such as 1200° C., as you see from the diagrams given of the Stockport engine here; but in such engines the mean pressure is lower than it would have been if some device such as exhaust or air super-compression had been used. The mean pressure indeed is lower by about 20 per cent. than it would have been. Another mode of overcoming this difficulty consists in injection of water into the cylinder during the compression stroke. This I understand is being used by Messrs. Crossley in accordance with a device of Banki, a Continental engineer.

Whatever device be used, when high compressions are required, it is necessary to look thoroughly to the cooling of every part of the engine, and to the admission of the working fluid at as low a temperature as is possible.

Although the pre-ignition is the greatest of the internal combustion motor difficulties in large engines, there are other troubles which occasionally give considerable annoyance. Sometimes an engine will ignite into the supply pipe. This is called a back ignition. This back ignition is due to the inflammation of the charge as it enters the cylinder by something which it encounters within the cylinder. Sometimes this something is found in the lingering flame from the previous explosion. This is always the case with diagrams like Fig. 13. In these diagrams the combustion rate is so slow that burning charge is still found in the cylinder, even on the beginning of the next suction stroke. The back ignition, however, may also be due occasionally to some incandescent matter within the cylinder, such as burning oil. It may be produced, for instance, by over-lubrication.

Another source of annoyance occasionally found is due to exhaust explosions. An exhaust explosion is caused by the missing of the ignition of the engine and the discharge of an unburned charge into the exhaust pipe and chamber. On the next ignition stroke the flame discharge through the exhaust valve sometimes ignites the accumulation which has passed into the exhaust pipes, and we hear heavy banging, as it is called. These troubles, however—back ignitions, exhaust explosions, and missed ignitions, are matters of little moment, compared to the pre-ignitions. They are now well under control. All good gas engines kept in reasonably good order entirely avoid them. All these troubles come in the main from over-heating.

It has often occurred to inventors to avoid all back ignition and other ordinary gas engine troubles by compressing air alone, and adding the inflammable charge just at the moment of completed compression. If this be done, there can of course be no pre-ignition. Pure air cannot ignite, however highly it may be compressed.

In 1887 I had an engine built on this principle, and Fig. 22 is a diagram taken from

Fig. 22.

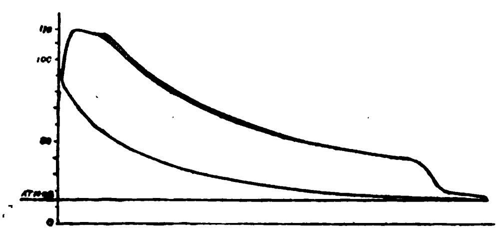


Diagram from Clerk Flame Engine, 1887.

it. This engine used ordinary coal gas, air alone was compressed in the cylinder, the gas was compressed separately by a side pump forced into the engine cylinder through a series of gas jets, and ignited exactly as it entered. This engine worked very well, but the mean pressures obtained were too low.

Herr Diesel took up the same idea somewhat later, and he endeavoured to apply it to both gas and oil engines. His attempts to apply it to gas engines have so far failed; but he has made a fair success in applying it to the oil engine. The difficulties, however, are very great. Diesel at first thought that he could produce an engine following the Carnot cycle. Ultimately he produced an engine of the constant pressure type, the theory of which follows the diagram shown at Fig. 3.

AGRICULTURAL AND INDUSTRIAL SETTLEMENTS.

The Rhodes Trustees having asked Mr. Secretary Lyttelton to nominate a Commission to proceed to the United States to inspect and report upon the condition and character of the agricultural and industrial settlements which have been established there by the Salvation Army, with a view to the transmigration of suitable persons from the great cities of the United States to the land, and the formation of agricultural communities, the Secretary of State for the Colonies nominated Mr. Rider Haggard, who left for New York at the end of February, and reported on May 5. It appeared to Mr. Lyttelton that if the Salvation Army experiments were found to be successful, "some analogous system might, with great advantage, be applied in transferring the urban populations of the United Kingdom to different parts of the British Empire." Accordingly, Mr. Haggard visited the Salvation Army Land Colonies situated respectively at Fort Romie, California, Fort Amity, Colorado, and Fort Herrick, Ohio. From the United States, Mr. Haggard proceeded to Canada, and, after consultation with the Dominion authorities, proposed a scheme of land settlement to Sir Wilfrid Laurier, by whom it was favourably received. Mr. Haggard asked the Dominion Government for a free grant of land suitable for settlement, and the Dominion Government has offered an area equal to ten townships, or 240,000 acres, say 360 square miles, with a promise of extra land to be given, if necessary, in the future. This area, allowing 160 acres per family, which is the ordinary Canadian homestead lot, would accommodate about 1,500 families, or, if an average of five persons is reckoned per family, 7,500 souls. The cost of the transportation, and the settling of that number of people in Canada, where the land is given, Mr. Haggard puts down roughly at £200 per family, or £300,000 in all. Mr. Haggard sought an expression of the willingness of the Canadian Government to assist in guaranteeing the interest on a loan which would provide the capital necessary to put the settlement scheme into operation, but this guarantee was not obtainable.

Mr. Haggard's inspection of the Salvation Army colonies has satisfied him that they have been "eminently successful," and that they warrant the belief that the congestion of our cities may be relieved, at any rate to some extent, "by exporting from them those who are physically, mentally, and in other ways suitable, and who are found to have fallen into or to be threatened with poverty, or who, being weary of towns, desire to attempt the adventure of a different life in new homes upon the land." But Mr. Haggard says that if the experiment is to succeed the colonists must be supervised, and he would entrust this work to the Salvation Army. "This vast organisation is, I am authorised to say upon its behalf, able and willing to make the selection of suitable settlers to any extent from among the poor of the cities of Great Britain, conducting their operations under the authority and direction of an Imperial officer, appointed, as I have suggested, to control them." As to the capital necessary to give the colonists a fair start, Mr. Haggard looks to the Imperial Government to provide the necessary guarantee, and he suggests that, "when this question of a guarantee comes up for discussion, it will be well worthy of consideration as to whether the large municipalities of the United Kingdom should not be asked in what shape they would be prepared to assist the movement so far as the law allows, or by emendation can be made to allow." Given sufficient capital, careful selection of the settlers and of the land, and skilled and sympathetic management of both after settlement, Mr. Haggard is confident that the suggested land colonies would be a success, an opinion from which probably few would dissent.

FACTORIES IN BRITISH INDIA IN 1902.

The latest return of Judicial and Administrative Statistics for British India,* compiled under the supervision of the Director-General of Statistics, deals with a variety of matters, such as criminal and civil justice, prisons, police, education, birth and death rates, lunacy, municipal activities and factories. Compared with the factory returns issued in New Zealand, the Indian statistics are lacking in several interesting particulars, such as capital outlay, value of raw material used, wages paid, and output, but give information of the order usually secured by inspectors of factories.

In addition to 84 factories owned by the State, or by local authorities, there are 1,389 undertakings worked by steam, and owned by companies or individuals. The former group covers 14 printing presses, 13 railway workshops, 11 canal and engineering workshops, together with a number of military arsenals and factories. The latter group contains 173 cotton mills, 39 jute mills, 67 cotton presses, 78 jute presses, 39 ironworks and foundries, 98 rice mills, and 64 saw mills. The cotton factories are located mainly in the Bombay Presidency, jute mills and presses in Bengal, while the rice mills and saw mills are mainly concerned with the exploitation of the two principal products of Burma—rice and teakwood. The average number of *employés* in 1902 consisted of 424,375 adult males, 85,882 adult females, 26,440 male children, and 4,937 female children. Of this total, 205,152 (or 38 per cent.) are employed in factories in Bengal, and 180,224 (or 33 per cent.) in Bombay, near three-fourths of the factory labour in India being employed in these two provinces.

The increase in factories seems fairly continuous, the number of adult males and other workers employed being as follows:—

* Published by the Office of the Superintendent of Government Printing, Calcutta, 1904, price 3s.

	Adult Males.	Women and Children.
1900	372,617	76,339
1901	408,950	104,266
1902	424,375	115,259

The number of accidents reported amounted to 3,107, of which 95 were fatal. Of these 37 occurred in Bombay and 33 in Bengal. Of serious accidents 194 occurred in Bengal, 102 in Burma, and 71 in Bombay. The largest number of minor accidents—1,491 out of a total of 2,517 occurred in Bombay. As regards offences against the Factory Acts, 24 convictions were secured, of which 7 were for the employment of persons in contravention of the Act, 6 for neglect of ventilation and cleanliness, 4 for neglect to send notices or returns, 3 for neglect to fence machinery, 3 for neglect to keep the prescribed register of children. and one for corrupt use of statistics.

THE TRADE AND INDUSTRIES OF NORWAY.

The long coast-line of Norway has always enabled her inhabitants to carry on a considerable trade with other countries, and, owing to improved communications, the exports of the country have rapidly increased both to European and Transatlantic markets. Experience has proved that Norwegian goods can hold their own in the world's markets, and, with the natural resources of the country, there is every reason to assume that the development will continue. According to a report just issued by the Trade Intelligence Bureau of Norway, the forests of that country form the basis of her high-class wooden articles, wood pulp, and paper industries; the utilisation of the immense quantities of fish contained in her seas also plays a very important part in the economy of the country. Agriculture has undergone a steady development, which has found expression in the export figures, and the vast sources of power of which the country is possessed in her waterfalls will give her industry a strong support on the markets of the world. Of the vast area of the country, 21 per cent. is covered with forests, and it is therefore natural that Norway should play an important part in supplying the world with timber. About 70,000,000 cubic feet of timber are exported annually. In addition, considerable quantities of wooden wares, such as joinery, cooper's wares, mouldings, &c., are exported. The export of Norwegian matches amounts to about 3,000 tons per annum. Special mention should be made of mechanical and chemical wood pulp, for which articles Norway is one of the chief centres of production. In 1904, Norway exported about 450,000 tons of her production of wood pulp to countries in, and beyond, Europe. The production of paper, chiefly printing paper, packing paper, and cardboard, is also of some importance. In 1904, the exportation of paper amounted to about 60,000 tons. The important coast fisheries yield the chief part of the fish products exported. First come the well-known articles of consumption, klip fish and stock fish. In 1904, nearly 31,000 tons of klip fish and 17,100 tons of stock fish were exported. A cheap and valued comestible is salt herring, of which there are considerable quuantities exported, as well as salt mackerel. Among other products of fishing and whaling may be mentioned fish oil, whalebone, and fish guano. Altogether, the exported products of seal, whale, and ordinary fisheries amount in value to about three millions sterling annually. The cultivation of the land has increased very considerably, and of agricultural products considerable quantities are exported. Special attention has been given to the development of cattle-breeding and of dairying. In 1904, 1,527 tons of Norwegian butter were exported, and 777 tons of margarine. Another article which is produced and exported in large quantities, is condensed milk, of which 11,000 tons were exported in 1904. Of the mining products, iron pyrites and copper are the most important. In 1904, 116,550 tons of iron pyrites and 2,700 tons of copper ore were exported. The new railway between Norway and Sweden, which terminates in the Norwegian town of Narvik, has made this seaport into a very important shipping centre for iron ore. Among other articles may be mentioned feldspar (exportation about 21,000 tons). The stone industry is also of some importance, both as regards pavings and stone for building purposes. About 190,000 tons of hewn stone are exported annually. The other branches of industry deserving of mention are the metal and machine industries, which in many respects have reached a remarkable degree of development, such as ship-building, the manufacture of horse-shoe and other nails, and the manufacture of machines and electrical appliances. Among the exported articles may also be included calcium carbide, which is largely produced, and of which 5,700 tons were exported in 1904, sulphur, vinegar, and acetic acid.

ORANGE INDUSTRY IN THE WEST INDIES.

The Imperial Department of Agriculture for the West Indies has printed a paper by Mr. H. Hesketh Bell, C.M.G., Administrator of Dominica, on the cultivation of oranges in Dominica, from which the following particulars are taken :—

Chief Orange Markets.—Oranges are produced more or less abundantly in all countries lying between latitudes of 40° north and south of the equator, but the world's great markets are chiefly supplied by fruit grown either in the Mediterranean, in California, or in Florida. Covent Garden relies for its principal supplies on Spain, Malta, and the country round Jaffa, while the demands of New York, Boston, and other great centres

of the Eastern States, are met by the products of the Pacific coast and of Southern Florida.

The magnitude of the orange trade may be realised when one considers that the annual imports into Great Britain comprise some 6,000,000 cases, amounting to a value of over £3,000,000, and that the output of California alone is not less than 9,000,000 cases a year. Owing to the occurrence of severe frosts and other disasters, the output of oranges from Florida has not increased in the same ratio as that of California, but the crop for this season is nevertheless estimated at about a million and a half boxes. The Cape and certain parts of Australia appear also to be suited to the production of citrus fruits, but, up to the present, the yield of these countries does not seem to be largely in excess of the local demand.

Natural Advantages of Dominica. — Land in Dominica suitable for growing oranges can be purchased almost anywhere in the island at prices varying from 10s. to £5 an acre. Owing to the generous rainfall, artificial irrigation is never necessary. The island's soil is proverbial for its fertility, while the climatic and meteorological conditions appear to be exactly suited to the successful cultivation of citrus trees. The wages of labour, instead of being from 4s. to 6s. a day, as in California and Florida, are barely a quarter of those rates, while the cost of living is proportionately low. Ample shipping opportunities exist for the conveyance of produce to Europe and America, and freight rates are not unreasonably high. Above all, it is being proved that oranges, under certain favourable conditions, can be produced in hill-districts far earlier in the season than is possible in California or on the Mediterranean, and the fruit may be placed upon the market at a time when supplies are short and prices correspondingly high. Judging by what Mr. Bell had seen of orange culture in Florida, the Bahama Islands, and in the Mediterranean, he believes that the local conditions in Dominica are far superior to those existing in most countries, and that a very promising and highly profitable industry may be founded.

Present Output of Oranges. — Dominica has, for many years past, been, more or less, an orange - producing country. There are fine trees scattered about, here and there, all over the island, and so greatly do they flourish by natural means that crops exceeding 5,000 fruits from individual trees are not uncommon. Such a yield anywhere else would be phenomenal, and we are thus encouraged to look for even more exceptional results when improved methods of cultivation are adopted. The export of oranges during recent years has varied between one and two millions of fruit, but in spite of this the industry has languished and cannot, in fact, be considered to have ever been taken up seriously. The results of shipments have usually been more or less unsatisfactory, and up to quite lately the possibility of a profitable orange trade was generally disbelieved. Mr. Bell attributes this stagnation in so promising an industry mainly to four causes; firstly, the complete absence of cultural methods; secondly, ignorance of the market's requirements; thirdly, inferior varieties; and, fourthly, rough and careless handling of the fruit.

During the past three years Mr. Bell made several experimental shipments of Dominica oranges not only to the London markets but also to New York. In making these shipments he was guided by information gained in Florida and in the Bahama Islands, and especially by notes made during rambles around Covent Garden market, and in chats with various fruit brokers. In most cases, the fruits were good typical specimens of the best Dominica oranges. The oranges were cured, graded, wrapped in attractive papers, and packed in the standard-sized Florida boxes, and the fruit arrived on the market in a shape no way differing from the usual American supplies which go to Covent Garden.

In September, 1903, six boxes, each containing on an average of 126 oranges, were sent to London. The brokers reported on them as being in excellent condition and of very fine flavour. They were sold by auction and realised from 10s. to 11s. 6d. a box. Apart from the cost of the fruit, the expenses for packing, wrappers, boxes, nails, export tax, freight to London and brokers' charges, amounted to a little under 4s. 6d. a box, thus leaving a margin of about 6s. for the value of the oranges contained in each package.

In November, 1903, seven boxes were sent to New York and sold for $13·25. The duty of $1·00 a box and the heavy Customs' charges swallowed up the profit, and this venture clearly proved that unless a higher price than $2 can be expected per box, shipments of oranges to New York can hardly be profitable.

The Jaffa orange can be highly recommended for culture in the West Indies. It is a large oval fruit of the first quality, the pulp is rich and juicy, there is little "rag," and seeds are frequently quite absent. The tree is very hardy, and bears early. There are several other varieties which appear to thrive admirably in these islands, and among them may be mentioned the "Parson Brown," the "Valencia Late," "Boone's Early," and the "Mediterranean Sweet." Any one starting an orange grove would do well to grow several varieties, and to give special attention to those which fruit very early or very late in the season.

The common sour orange, often found growing wild in Dominica, has been proved to provide the most suitable root-stocks for orange culture in the West Indies. Some nurserymen favour "rough lemons," but the one just mentioned is certainly the most vigorous and the most resistant to "collar-rot" or "mal-di-gomma." The fruit of the sour orange can be readily obtained here, and at almost nominal cost, during the last three months of the year. They must be perfectly ripe, and the seeds should be planted very soon after they have been

extracted from the fruit. They should be sown about 1 inch apart in drills 6 inches apart, and covered with ½ inch depth of soil. If very dry, hot weather be expected, a light screen of reeds or brushwood can, with advantage, be erected over the seed beds. The seeds should germinate in sixteen to twenty days, and the beds must be kept entirely free from weeds. In four to six months, the young seedlings should be about 6 inches high, and therefore fit for transplanting. Long, straight beds to receive them will in the meantime have been prepared, and into these the young plants should be moved, being set out in two or three rows, not less than 18 inches apart.

Conditions of Cultivation. — Although orange trees appear to thrive in Dominica, under almost any conditions, and where few other products would grow, still it is only reasonable to expect that far greater and more rapid results would be obtained where everything is favourable to good cultivation. Ideal conditions for an orange grove in this island would appear to be the following:—Altitude varying from 800 to 2,000 feet. Proximity to a good road and within easy distance of the shipping port. A gentle slope with a south or westerly aspect, and consequently well sheltered from prevailing winds. A rainfall of not less than 100 inches a year. A dark, friable soil, rich in phosphates and nitrogen, and thoroughly well drained.

Under such conditions and with good management, an orange grove should prove a very remunerative venture. Among the 100,000 acres of virgin land, which this island still possesses in the mountains and valleys of the interior, it ought to be no difficult matter to find considerable areas fulfilling every one of the requirements indicated.

Scale Insects. — In California, in Florida, and in most other great orange-producing countries, the planter is grievously plagued by various pests. He has to contend against the scale insects of all colours and of exceeding virulence, and it is only by a vigorous and permanent campaign that he manages to defeat their continuous attacks. Here, in Dominica, we are, so far, in the enviable position of suffering comparatively little from insect pests. Although there are in the West Indies no less than 120 known species of scale insects, only twenty-four of them are found in this island. Their numbers are, however, undoubtedly on the increase, and they constitute one of the chief dangers to a successful industry in oranges. It seems as if the budded varieties are far more liable to the attacks of scale insects than are the indigenous trees, and great vigilance is necessary to keep them free of pests.

Packing.—The wisdom of packing oranges only in boxes of standard size has been proved over and over again, and the use of barrels or rough-and-ready crates cannot be too strongly deprecated. The standard orange box, to which all the chief markets of the world are accustomed, measures 12½ by 12½ by 27 inches, outside measure, with a partition in the middle. The slats and sides for these packages can be bought in America, and the cost, f.o.b. at New York, is about 5d. per box. The Pierpont Co., Savannah, U.S.A., can be recommended.

The packer should very carefully examine every fruit, and discard every one that is in the least bruised, discoloured, or unsightly. Every orange should be neatly wrapped in white tissue paper, and carefully packed in layers. The top layer should project about ½ inch above the sides of the box, which will make the packing close after the cover is nailed on under gentle pressure. Every box should be stencilled on both ends, showing the grower's brand, the number of oranges in the package, and the quality. It is a well-known fact that a box of fruit nearly always sells on the merit of the poorest specimen contained in it. It behoves the grower, therefore, to spare no pains to ensure uniformity of quality in his produce. The following golden rules cannot be too strictly observed: "Grade carefully, pack firmly, and never ship an inferior fruit." The planter who follows these rules will soon get a good name on the market, and will always command a high price for his fruit.

Yield.—A grove of budded oranges will bear fruit very early. If well cultivated and healthy the trees will begin to produce a few oranges in their third year, and an average of fifty fruits per tree may reasonably be expected in the fourth year, with a steady and heavy increase in every succeeding season. In California and in Florida, two boxes per tree—that is to say, from 300 to 400 fruits—are expected in the sixth or seventh year of an orange grove, with a proportionately higher yield as the tree grow older. There is reason to believe, as I have already remarked, that the natural conditions found in the West Indies are far more propitious to orange culture than those of most other parts of the world, and I daresay that many of my hearers know of orange trees growing in Dominica which yield over 5,000 fruits each year. One of my budded trees at Sylvania gave last October 275 fruits, although it was only in its fourth year, and a crop of 400 oranges per tree in the seventh year may therefore not be, by any means, an excessive estimate for orange groves in this island. Calculating on that assumption, an acre of 100 trees, seven years old, should yield 40,000 oranges, equal to about 220 boxes. We have already seen that 4s. to 5s. per case is a reasonable and average net profit to expect on shipments of oranges of fair quality, and, at that rate, the produce from an acre should represent a value of about £45. The annual cost of cultivating an acre of orange trees in bearing should not exceed £4 a year, and expenditure on such a scale would allow for a liberal outlay on manures, spraying, and general care of trees. It will, therefore, be seen that a grove in Dominica may be expected to yield very handsome results.

The foregoing calculations are based on the assumption that the oranges produced will only be worth an average of 10s. a case, but where fancy

varieties, such as seedless oranges are grown, far handsomer results may be expected. "Washington Navels" and "Jaffas" will easily fetch from 15s. to 25s. a case. The cost of cultivation and transport would be no higher than in the case of inferior varieties, and the margin of profit would probably be much greater. There appears, therefore, no ground for refusing to believe that the annual return of £100 per acre often earned in California, Florida, and Australia, may not also be expected in Dominica.

GENERAL NOTES.

INSTITUTION OF NAVAL ARCHITECTS. — The summer meeting of this Institution will be held in London. Papers will be read at meetings at the Society of Arts on July 19th, 20th, and 21st. Visits to the works of Messrs. Siemens Bros. and Co., Telegraph Cable and Electrical Instrument Works, near Woolwich; Messrs. Vickers, Sons and Maxim, Ordnance Works, Erith; and Messrs. and E. Hall, Refrigerating Machinery Works, Dartford, are arranged for Wednesday afternoon. July 19th. On Thursday, July 20th, visits are arranged to R.M S. *India*, of the P. and O. Steamship Company; H.M.S. *Black Prince*, built by the Thames Ironworks Company, now fitting out in the Victoria Dock; Messrs. Yarrow and Co., Poplar; and to Messrs. Thornycroft and Co. Chiswick. On Friday, July 21st, there will be the visit to Portsmouth Dockyard.

RABIES.—Opinion was sharply divided as to Mr. Long's action in muzzling dogs, but it stamped out rabies. In his report just issued (Cd. 2454), the Chief Veterinary Officer is able to say that "this disease has been entirely extinguished in Great Britain, no case having occurred during 1904, and not a single individual has died of hydrophobia. Suspected cases of rabies in the dog have been reported in 1903 and 1904, but the results of the inoculation test with portions of the brain of all these suspected cases have proved to be negative in every instance." Mr. Cope considers that there are good reasons for believing that this terrible disease will never again appear in this country, as the regulations which apply to the landing of dogs from abroad are of so strict a character that a comparatively small number are now imported, and those which are admitted are kept under veterinary supervision for a period not exceeding six months. In certain cases the Board are prepared to sanction the removal of an imported dog, during the period of quarantine, to private premises, but in every such case the dog is required to wear a leather harness of a pattern approved by the Board, and may not be absent from the private premises unless it is also muzzled. While on a highway or thoroughfare, or while being moved by railway, the dog is required also to be controlled by a collar and a chain, or other attachment.

CO-OPERATIVE STORES IN GERMANY. — The system of co-operative stores ("Konsum Vereine") in Germany, through which the labouring classes especially have effected so great a saving in the past, is being more and more bitterly assailed by the shopkeepers, who are ever seeking Government aid in endeavouring to arrest the further spread of an institution by means of which their trade is being rapidly undermined. It is insisted on their part that all Government *employés* should be restrained from joining or forming such associations, and a counter-movement be thus inaugurated. Those interested in the scheme, however, are not being deterred, they have taken steps to strengthen their solidarity of interest, and now propose to pass from the plan of buying their supplies from the manufacturer direct to the still bolder scheme of becoming the manufacturers of needed supplies themselves. According to the latest statistics, these associations in Germany now embrace 628 separate organisations, with a total membership of 480,000, and an annual turnover of £6,000,000.

THR TRADE OF TANGIER.—Mr. Acting-Consul Wyldbore Smith's Report on the Trade of Tangier for 1904 (No. 3426, Annual Series) shows a considerable shrinkage, due mainly to the disturbed state of the neighbouring district, which resulted in the road between Tangier and Fez being so insecure that merchants were unable to send goods by this road to Fez at any time of the year, and to a bad harvest. The United Kingdom did not do quite as well as in 1903. British trade, on account of its staple imports being those which are most in native demand, such as cotton goods, candles, tea, &c., depends, almost more than that of any other nation, on the native consumption and on the Fez market, both of which sources of prosperity for British import trade have greatly diminished by the reasons above stated. On the other hand, Germany benefited by the large amount of cheap cloth imported, which, owing to the impecunious state of the natives, was in much greater demand than the more expensive British material. Nevertheless we find that the imports from the United Kingdom were 33¾ per cent. of the whole, whilst from Germany they were only 8 per cent. Of the exports the United Kingdom took 25 per cent., and Germany only 1½. Mr. Consul Smith says that with the steady influx of Europeans to Tangier, a great demand for furniture has sprung up, cheap, light furniture, such as stained wood and bamboo and basket work goods. Owing to the failure of the harvest, and the withdrawal of the Sultan's permission for coastwise trade, there is, the Consul says, a great demand for flour, and especially semolina. French and Italian millers are reaping a rich harvest, in which British millers might have a good share.

NOTICES.

COLONIAL SECTION COMMITTEE.

A meeting of the Committee of the Colonial Section was held on Wednesday afternoon, 19th inst. Present:—Sir Westby B. Perceval, K.C.M.G. (Chairman of the Committee), in the chair, Byron Brenan, C.M.G., Hon. Sir John A. Cockburn, K.C.M.G., Robert Kaye Gray, Hon. Walter Hartwell James, K.C., Agent-General for Western Australia, Sir E. Montague Nelson, K.C.M.G., Earl of Stamford, with Sir Henry Trueman Wood, M.A., Secretary of the Society, and S. Digby, Secretary of the Section.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

INTERNAL COMBUSTION ENGINES.

By Dugald Clerk, M.Inst.C.E.

Lecture III.—Delivered February 27th, 1905.

Syllabus.

Examples of Internal Combustion Engines in Britain.—Clerk cycle engines, Koerting, Oechelhauser—Constant pressure cycle engines—Coal gas, producer gas, and blast furnace gas engines, Crossley, National, Premier, Cockerill, Deutz.

In my last lecture I dealt with the various questions which bore upon the economy and operations of the Otto cycle engines. I spent nearly the whole evening considering their cycle; so now I propose to take up first the Clerk cycle and its modifications, the Koerting and the Oechelhauser, and then the constant pressure engines, like the Brayton and the Diesel, and other engines of that type. As I have gone fairly fully into the particular points on the Otto cycle, I need not trouble you with such minuteness to-night upon the Clerk and the other cycles, so I will run rather quickly over those matters, so as to show photographs, and discuss some of the practical points in connection with the large gas engines.

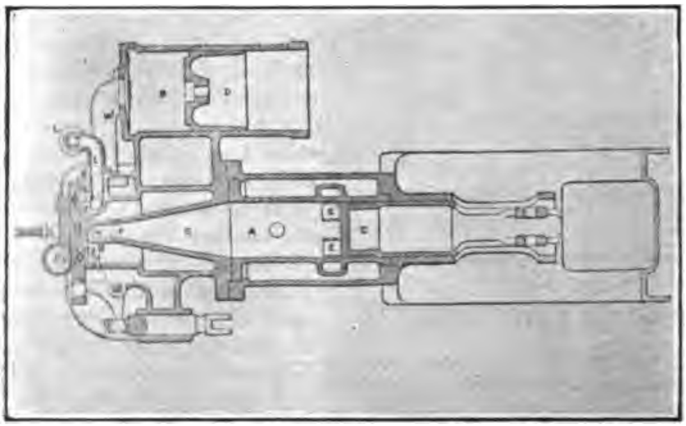
To begin with the Clerk cycle engine: this engine is not so well known to-day as it was more than twenty years ago, so I think it desirable to describe it with reference to Fig. 23, which is a sectional plan. In the Clerk engine the motor cylinder had, at the front end, large ports leading into an annular space, these being the exhaust ports. The compression space was conical, and the charge was sent in by means of a separate pump, which I called the displacer. The action of the engine was as follows:—When the piston got to the out end of its stroke, and the crank was crossing the out centre, the piston overran the exhaust ports on the out-stroke, and covered them on the in-stroke. Meantime the pump or the displacer piston, which was attached to a crank at right angles in advance of the main crank, was sweeping in and giving its charge a slight compression. That charge passed through a connecting pipe, and through a check valve, into the conical end, displacing before it all the contents of the cylinder. When the main crank had returned about 40 degrees of its circle under the centre, these ports were closed. It opened about 40 degrees above and closed 40 degrees under, and in that time the displacer piston had gone fully in and discharged its charge into the cylinder and combustion space through the lift valve. Then the motor piston compressed the charge, and ignition took place at the in end of the stroke, just as in the Otto cycle. The object of the invention was to enable one motor cylinder to give an impulse at every revolution. In the Otto cycle there is only one impulse for two revolutions, so far as the main cylinder is concerned. The Clerk engine gave one impulse for every revolution of the main crank in the main cylinder, but, to make that possible it was necessary to provide an auxiliary crank and displacer cylinder. The idea, was, of course, to diminish the irregu-

arity of the Otto cycle by having an impulse at every revolution, or more frequently, that is to say, two impulses per revolution, obtained by making the engine double acting. The object was to get very much more power for a given weight of engine, as the pump was light and only required to deal with its charge at a low pressure. In construction the engine was a very simple one.

Fig. 24 compares the diagrams obtained from the Clerk and the Otto cycles. In the four stroke cycle diagram there is clearly seen the charging stroke, the compression stroke, the explosion and the expansion, and then the point of opening the exhaust valve and exhausting the burnt gases. In the two stroke or Clerk diagram there is nothing shown upon the main indicator card of the charging stroke, because immediately the piston overruns the exhaust ports the pressure falls almost to atmosphere, and then the displacer piston at right angles in advance of the main crank discharges its charge into the cylinder while the main crank is crossing the centre. Compression of the charge then takes place, and ignition, expansion and exhaust follow as I have described.

In the Clerk cycle engines the considerations which govern power and economy very closely resemble those of the Otto cycle, but there are several points which require to be carefully considered—points, indeed, of considerable difficulty—with regard to which the Otto cycle is a far easier cycle than the Clerk cycle. In the Clerk cycle, the charging has to be accomplished in the motor cylinder, while the crank is passing through an angle of about 80 degrees. Sometime a little larger angle is allowed, but, roughly, 80 degrees of the crank angle is the limit for charging of the motor cylinder. Because of this, much larger inlet valves and very much larger discharge areas are required in the Clerk than in the Otto cycle. In the Otto cycle the charging stroke occupies not only the whole of one stroke, which amounts to 180 degrees of the crank movement, but in addition a further 40 degrees, which permits the inlet valve to be held open considerably over the out centre, and also to be opened a little before the centre on the in-stroke. In consequence, the Otto type of engines allows three times the time interval to charge the cylinder, at a given rate of revolution, that it is possible to allow in the Clerk cycle. For a given valve area, the velocity of charge entrance in the Otto cycle is about a third of that in the Clerk cycle. This means that the Clerk cycle engines are more difficult to charge, and require greater power expenditure to charge the cylinder than the Otto cycle. That is the great weakness of the Clerk cycle as constructed at present.

FIG. 23.

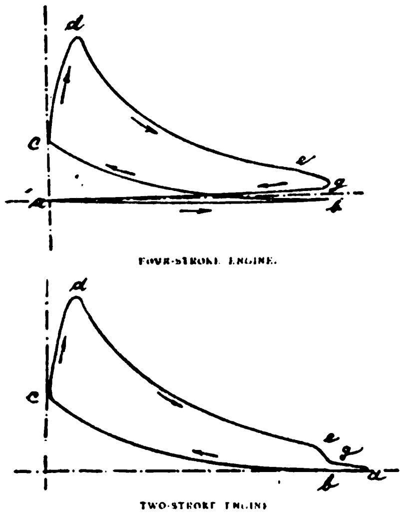


SECTIONAL PLAN OF CLERK CYCLE ENGINE, 1881.

Then there is this further point. In the Otto engine, when the piston moves out, taking in its charge, there is no question of any possible discharge at the exhaust ports, because the piston is sucking in the charge by a partial slight deficit of atmospheric pressure, and there is no exhaust port open through which fresh charge may be lost. In the Clerk cycle, the proportions of displacer and motor cylinder have to be very accurately ascer-

tained, otherwise part of the charge entering the cylinder is apt to pass right down through the centre of the exhaust gases which are being displaced, and pass out of the exhaust port. That was overcome in the early Clerk engines by the peculiar conical shape of cylinder end, which has been since consistently adhered to in all the engines operating on the Clerk cycle. That difficulty, however, is met in two ways. One way is to put in a smaller charge than in the Otto cycle, but that has the disadvantage of leaving too much exhaust gas, and also giving you a smaller power of engine. Conse-

FIG. 24.



COMPARATIVE INDICATOR DIAGRAMS FROM ENGINES WORKING ON THE CLERK AND OTTO CYCLES.

quently, every designer of the Clerk cycle engine attempts to get in the full charge. The best method is to send into the cylinder, first a good heavy charge of air to displace the exhaust products, and then to follow it with a somewhat strong charge of gas and air. That is what I did in 1881, and that is what is being done to-day in all the large gas engines. That, however, is a somewhat difficult thing to do. The consequence is that if one of these cylinders be charged as fully as it would be in an Otto cycle, a slight proportion of gas is lost at the exhaust ports, and although in a small engine with a comparatively light load, the economy very closely approaches the best Otto economy, yet the maximum efficiencies that are possible with the Otto cycle have not been obtained with any two cycle engines. Because of this, the Clerk cycle has been reserved for somewhat special uses. It has come into extensive use of recent years in connection with large blast furnace gas engines.

The modern representative of the Clerk cycle engine is known as the "Koerting" engine, a German production, but so far as its essentials are concerned, it was invented in England twenty-three years ago. The engine is shown in Fig. 25. The charge is admitted at the inlet valves placed at the conical ends of the cylinder, and instead of having one pump for gas and air mixed, two pumps are provided, one of which is for gas, and the other for air. This engine, instead of being single-acting as the Clerk engine was, is double-acting, so that, so far as the main crank is concerned, there are two impulses every revolution just as there are in a steam engine.

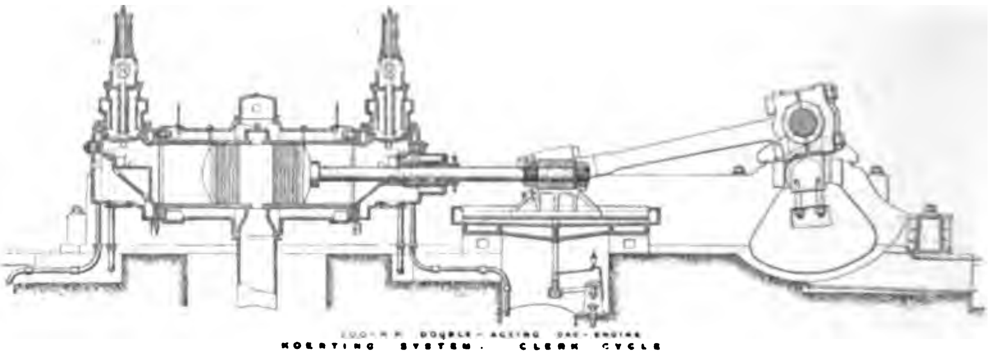
In this Koerting engine, the piston in the position shown is overrunning the exhaust ports at one end of its stroke, allowing the pressure in the cylinder to fall to that of atmosphere.

Fig. 26 is the diagram of the engine, showing the fall to atmosphere just at the point where the piston overruns the ports. Then immediately the pressure has fallen to atmosphere (this requiring about 20 degrees movement of the crank) the charge inlet valve is opened and air is first pumped in from the air pump. After the air has been flowing in for some little time to throw the exhaust gases forward, the gas is pumped in from the same valve, so that no mixture is made until the gas and air mixture enters the cylinder. That is a very important point. In a small engine the gas and air may be mixed in the pump, but in a large engine the charge of gas and air must be mixed just as it enters the cylinder. In a small engine an occasional back ignition into the displacer is no great matter; in a large engine it will be a serious matter; so that in the large engine the gas and air are kept separate until they flow into the motor cylinder. When the charge has entered, air first and then gas and air, and has displaced the exhaust products, the piston is closing the ports which shut off the exhaust after a movement of about 40 degrees of the crank; the compression then proceeds, and ignition and expansion take place, so that an impulse is obtained at every forward stroke behind the piston, and at every backward stroke in front of the piston. If it were possible to charge the cylinder with absolute certainty, without any chance of loss at the exhaust, there would be a great deal to be said for this cycle,

because it undoubtedly gives a very powerful engine for a comparatively light weight, and in very large engines the question of economy is not the pressing question. In large engines the pressing question is to get an engine that will run without breakdown. The amount of experience accumulated in the world with large engines is not as yet sufficiently great for the engineer to assure himself that, when he designs a big engine, it will work as smoothly and uniformly and with as little expense for up-keep as a large steam engine. It would be rather unnatural is about 1-6th of a second—between one explosion and the other. In the Clerk cycle engine the metal has no such rest: immediately the one explosion has finished, the new charge is put in and compressed and exploded again, so that the metal is strained somewhat more than on the Otto cycle, although that is not found to be a very serious point.

Now, in addition to the Koerting engine, there is another engine somewhat on the same lines; that is, an engine in which the exhaust gases are displaced through ports in the side of the cylinder by the entering charge. In

FIG. 25.



at this present stage of the career of the large gas engine, if it did work so uniformly and smoothly. As a matter of fact, the larger engines are very rapidly improving, but as yet there are many difficulties apart altogether from economy, so that, although one is discussing the economical points of these engines, it must not be thought that the point of economy is by any means the leading point with regard to very large engines. In addition to the difficulty of charging the Koerting engine, due to the fact that the cylinder can only be charged through a small crank angle, there is a further difficulty due to the fact that, for a given flame temperature, there are double the number of flame impulses upon the piston in a given number of revolutions. The effect of this is that, in the Otto cycle, although there may be a watered piston, still it does not matter whether the piston is watered or not, or whether the jacket is watered or not; but in these large engines the terrible flow of heat through the side walls causes, undoubtedly, a severe strain on the metal. In the Otto cycle, all the metallic parts which have been highly heated by an explosion, have a rest of a fraction of a second, which, it is true, is not very much in an engine of 160 revolutions—it

the Oechelhauser engine shown in Fig. 27, that is what is done. It is a very interesting engine, and it runs with great smoothness. I had the pleasure of inspecting several Oechelhauser engines in Germany some time ago. The engine has two opposing pistons,

FIG. 26.

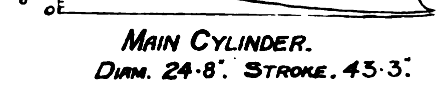


DIAGRAM FROM KOERTING ENGINE.

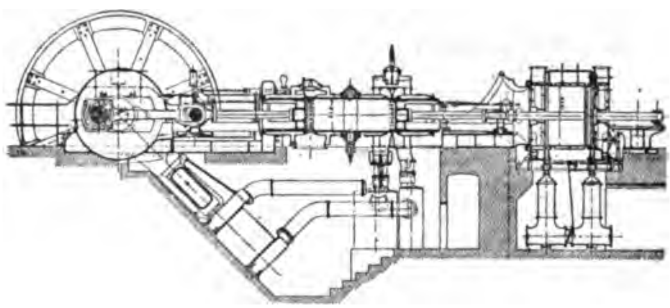
driven from a crank in the front part of the engine; there are three crank pins, one the main crank pin driving the front piston; then outside of that there are two other crank pins, disposed exactly opposite, that is, 180 degrees from the main crank. These two opposite pins drive separate side rods and

cross-head, and the two pistons therefore move out at equal velocity. This arrangement produces a very nicely balanced engine, all the strain of the explosion being removed from the frame, and taken by the cranks only. The two pistons overrun the ports, the one at one end and the other at the other. In the front end, the piston overruns the exhaust ports, and the pressure falls to atmosphere exactly as it does in the Clerk and the Koerting engines. A little later the back piston is overrunning the air ports, shown in Fig. 27, as a series of holes. The air is accumulated by means of a pumping arrangement, and this air first runs into the cylinder from ports placed all round it, driving out the exhaust gases. In this way the cylinder is cleared of the hot incandescent matter before the gas enters. Then as the piston moves further back the next ports are uncovered, and the gas enters, coming from a separate reservoir. The mixture of gas and air runs right up to the cylinder, and discharges the exhaust gases and the air that has been put in first; then compression takes place, and then ignition, expansion, and so on, just as in the other cycles. The engine illustrated is a blowing engine for a blast furnace, the blowing cylinder being directly coupled on to the piston rod. This engine has one great advantage over other forms of engine working on the Clerk cycle, viz., that there are no valves so far as the combustion and explosion is concerned except the pistons themselves. The two pistons form the whole of the valve arrangements, and no pressure of explosion can come on any other valve. There are no lift valves exposed to the consequences of the explosion, so that a very large valve area may be allowed. The engine, however, has disadvantages. It is a more expensive engine to build, and a very considerable weight of metal is required for a given power, but it is a very smooth-running engine, and, although it does not come up quite to the Otto cycle in economy, it has given great satisfaction in Germany, and is, I believe, running very well in England from the point of view of requiring but little repair. The well-balanced pistons, and the fact that only wide open ports are overrun by the pistons, make it eminently suitable for gases such as blast-furnace gas, which would always carry a slight amount of dust with it.

Another modification of this type of engine is found in the Day engine, which was produced many years ago: it was called a valveless engine. In this engine the front end of the cylinder and the crank was enclosed in a casing, very much like the modern petrol engine, and the front end was used to take in charge which was to displace the exhaust products at the back. The consequence of that arrangement was that you could run the engine with an impulse at every revolution without the displacer. Many engineers in America have taken up that particular modification of the Clerk cycle, and it is very commonly used for small launches and marine work; but one often sees in motor and other papers that great surprise is expressed that more power is not obtained from an engine of the type. The reason is clear. If the piston of the engine displaces only its own volume of charge into a comparatively large space, when the clearance is great and the pressure in that space falls, the whole of the contents of that space, owing to the large clearance, cannot possibly be discharged, and only about two-thirds of the piston stroke charge passes in behind the piston. The consequence is that we have a

FIG. 27



SECTIONAL ELEVATION OF OECHELHAUSER GAS BLOWING ENGINE.

charge which is one-third less than the Otto charge, and a larger proportion of the exhaust. This makes it necessary to use lower compressions in order to avoid pre-ignition. The general effect of that cycle is that instead of getting, as in the Otto cycle, a mean pressure in a small engine of 80 lbs. on the square inch, not more than say 45 lbs. to 50 lbs. is obtained, and then, although there is an impulse every revolution, nothing like double the power of the Otto cycle is obtained, and the front casing must be made heavier. If any engine is to give the full average pressure possible, some device such as I have used, to give the full charge, must be provided. This may be done on the Clerk cycle with a displacer, because the displacer may be regulated as desired, but it cannot be done in these little American engines.

I have now run quickly through the different points of the Clerk cycle, that is, the points wherein that cycle differs from the Otto. So far as the ideal efficiency is concerned, the formula given in the first lecture holds for the Clerk cycle as well. The only difference is that the difficulties in keeping down the temperature of the charge are much greater in the Koerting and Clerk cycle than in the Otto.

In dealing with the constant-pressure engine, it will be well to bear in mind the formula, now well established, for the ideal efficiency of the constant-volume engine, that is, the Otto cycle and the Clerk cycle, in the case where expansion is carried to the volume occupied by the charge before compression. The efficiency of engines of that type is—

$$E = 1 - \left(\frac{1}{r}\right)^{\cdot 408}$$

In the constant-pressure cycle, where expansion is carried to the same pressure as before compression, the ideal efficiency is given by the same formula. In the Diesel, or the constant-pressure cycle, where expansion is not carried to atmospheric pressure, the efficiency is different, it is as follows :—

$$E = 1 - \frac{T_1 - T_0}{1{\cdot}408\,(T_x - T_c)}$$

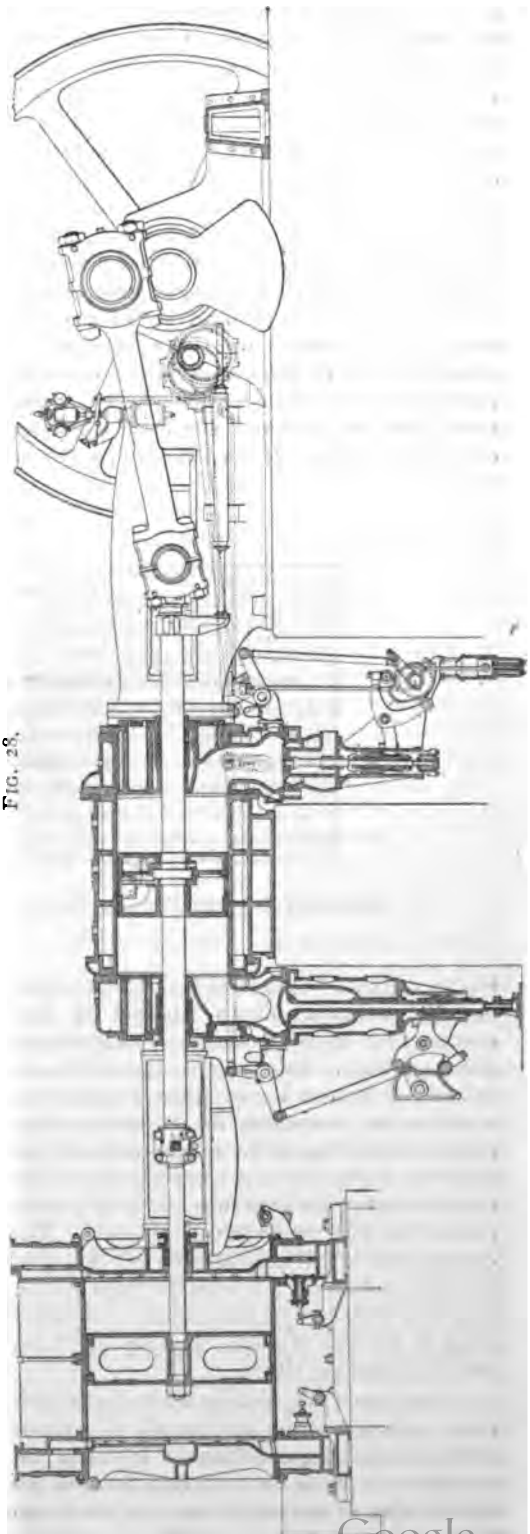
In this formula which I worked out some little time ago, T_0 is the temperature of the charge before compression; T_c is the temperature on compression; 1·408 is the ratio of the specific heats; T_x is the maximum temperature of combustion; and T_1 is the temperature at the end of the expansion. You see that in this case there is a much more complicated formula than the formula in the constant volume cycle.

Diesel started with some erroneous notions as to what he was going to do; his idea was that he was going to follow the Carnot cycle. In the Diesel engine the piston takes in just as on the Otto cycle (it can work on that cycle, or on any other cycle) a charge of air only—not gas and air, but air only. It compresses that charge up to a pressure of about 500 lbs. per square inch. At that pressure the temperature of adiabatic compression is so high, something in the neighbourhood of 700 degrees Centigrade, that any oil injected into the cylinder with air at once ignites without the use of any outside igniter. Diesel thought he was going on the Carnot cycle, but what he, in fact, did, was to get the advantages of the constant pressure cycle without the danger of pre-ignition or explosion or compression by having air in the cylinder only. Of course, it is impossible to pre-ignite, because there is nothing to burn in the air. Oil and air were added by means of a sprayer when the compression was complete, the air being previously compressed to about 150 lbs. to the square inch above the pressure in the cylinder, that is to say, 650 lbs. On injection of the oil, ignition takes place and then expansion.

In his description of the engine which he called a Rational Heat Motor, Diesel suggested that other inventors or designers of engines were proceeding upon wrong principles, and that the right principle was to rise to the maximum temperature by compression, add heat at the maximum, and have no increase in temperature after your compression. In his first engine, he thought he had done that; but it is obvious that if it is desired to follow the Carnot cycle, instead of having a pressure of about 50 atmospheres to get the maximum temperature used in this engine, a pressure of about 200 atmospheres is required. That, of course, means that heat must be added on the expanding line. Working on the Carnot cycle, as I showed in my first lecture, an extremely slender diagram is obtained, and an enormously heavy engine is required. Diesel did not notice what has recently been noticed, that the efficiency of the Carnot cycle, constant volume and constant pressure engines are all exactly the same if you have the same compression. The consequence is, that you gain nothing by going to the Carnot cycle. Diesel, in some of his recent papers, still adheres to the idea that he is dealing with a modified Carnot cycle, but all heat

engines may be considered as modified Carnot cycles, one as well as another. Twenty years ago I was in the habit of drawing Carnot cycles, and of cutting out a slice to represent any given engine. If you take the Carnot cycle, and take the compression curve, and take a vertical line for heat addition, you have the constant-volume engine. If you take the Carnot cycle, and add heat along a horizontal line, you have a constant-pressure engine. You can carve out of the Carnot cycle any engine you like, but you must not say, when you have carved an engine to suit your own convenience, that you are now working a Carnot cycle, and that the engine is therefore different from any other. What Diesel has, in fact, done is to use very high compressions on the constant - pressure cycle, on the formula which I have given above. Many attempts have been made to carry out constant-pressure engines for gas. Diesel has tried them. I myself built an engine in 1887, a diagram from which is reproduced at Fig. 22 (see previous lecture). This was a constant - pressure engine, or a modification of constant pressure and constant volume, somewhat like Diesel. In 1888 I had an engine of 9-inch cylinder, 15 inches stroke, with a compression space into which air alone was compressed. The ordinary coal gas was taken into a separate pump, working at about 50 degrees behind the main crank; this gas was compressed and ejected into the air when compression was complete, but I arranged a peculiar igniting device, so schemed that immediately the gas began to flow into the air it ignited, so that there was no explosion, but only the constant-pressure combustion. That engine worked extremely well. It was running well in 1888 for more than six months, and was perfectly free from gas-engine troubles, but the difficulty was that, with economy, only very low average pressures could be obtained. The average pressures I obtained with this engine were in the region of 30 lbs. to 40 lbs., instead of 70 lbs. to 80 lbs., as then obtained with the Otto cycle, or 90 lbs., as now usual. So far as that cycle is concerned, there is no doubt that a great deal has to be done yet in the way of constant-pressure engines. Many people have tried, including Diesel himself, but so far the difficulties have been too great to put any succcessful engine on the market. Brayton, in 1878, produced a gas engine of the constant-pressure type, but he compressed his gas and air separately into reservoirs to feed his cylinders at constant pressure. This

FIG. 28.

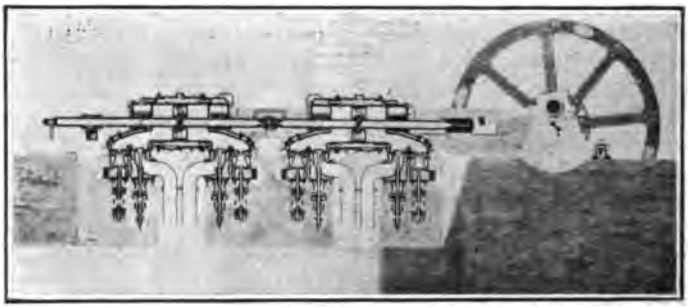


1800-H.P. COCKERILL GAS-ENGINE.

engine, however, was rather troublesome; it gave frequent back explosions, and there were two or three rather bad accidents with it. So far as oil was concerned, his engine was fairly successful, but he never succeeded with gas, the reason being that all constant-pressure engines, whether of the Brayton type, or of the Diesel type, or of the old type I tried, require gas to be stored up under enormous pressures. The gas before being mixed with air must be compressed to the full pressure. If we take, for instance, a cool mixture of gas and air, and apply compression to the full pressure, on ignition we get a pressure of about two tons on the square inch, a pressure which would require extremely heavy reservoirs. This is, perhaps, the chief difficulty of the Diesel type. If the charge in a Diesel engine happens to get in at high temperature, and the cylinder misses ignition by any chance, as I believe in the early experiments it did—at least, I should have expected it to do so, and I believe it did—then an explosion would occur. Supposing the mixture is compressed to 500 lbs. on the square inch only, an explosion occurs, and a comparatively small rise of temperature soon runs up the maximum pressure to one ton on the square inch. The consequence is that you really do get explosion and not combustion. That is the main reason why the constant-pressure type has never come in for gas engines. Nobody has been able to control the effect.

I want to run over quickly a few of the ordinary engines, because you are all so familiar with the ordinary gas engines. It will be unnecessary for me to do more than refer to the smaller sizes of engines of this sort, about 100 horse, mere matters of ordinary commercial daily work.* These engines are not so interesting because we have overcome all the difficulties. It was not true at one time to say that the difficulties were overcome, but now it may be said that up to 300 horse our difficulties have been overcome in gas engines, and the difficulties begin at about 300 horse and above Below that everything is absolutely dividend paying; but above that in large engines there is undoubtedly considerable room for difference of opinion, to say the least of it, among different engineers, and engineers are fighting out the battle of the big engine at present. I have no doubt that in a very short time they will be found to be quite as efficient as the smaller ones; but one cannot pretend that they are really in the position of the small engines that we turn out in great numbers.

FIG. 29.



VERTICAL SECTION TANDEM DOUBLE CYLINDER ENGINE. COCKERILL TYPE.

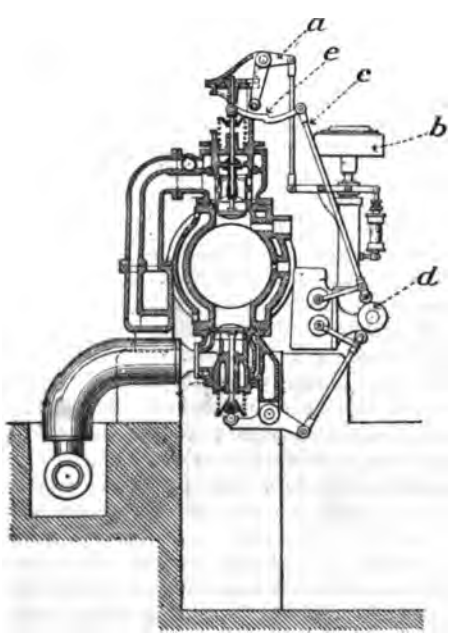
We now come to really large engines. The great difficulty at present in the large gas engines is that they are much too large for the power one gets. Fig. 28 shows a 1,200 horse Cockerill two cylinder engine. This engine gives an impulse at every revolution. In the Cockerill engine two separate valves are provided outside the main inlet valves, one for air and one for gas. The object of this is to arrange matters so that blast furnace gas can be used in these large engines. It does not do to allow any chance of air getting back into the gas end, or the gas end going to the air.

There is a very large installation of six Cockerill engines at the Cargo Fleet Iron Company works at Middlesbrough, each giving 900

* Lantern slides and photographs were shown of the following engines of various sizes with their indicator diagrams: Koerting, Oechelhauser, Diesel, Crossley, National, Premier, Cockerill, Deutz.

horse-power, so that the total horse-power is 5,400. These engines are the first built by Messrs. Richardsons, Westgarth, and Co., in England. They are extremely well thought out, and work satisfactorily. Fig. 29 shows an example of the tandem double cylinder engine, double acting, of the Cockerill type, at Messrs. Cochrane's at Middlesborough. The crank axle is placed at one end of the engine, which is provided with two double-acting cylinders, arranged tandem, the piston being carried right through. The valves admitting to the

FIG. 30.



SECTION OF VALVE BOX DEUTZ GAS ENGINE.

cylinders are arranged below the engine. This, however, is rather an objectionable arrangement, because the great difficulty in these large gas engines lies in the strains introduced by expansion, and everything should tend to allow of perfectly free expansion. A great many of the troubles we have met with have been due to failure to realise the intense temperature of the explosion and expansion. For instance, taking the engine shown in Fig. 29, there is a combustion chamber about three or four feet long, and the metal must be strained very badly indeed. In later engines the makers have improved the engine in this respect by placing the valves at the top and bottom. Difficulties such as these cannot, however, be thrashed out except on a large and extensive scale on the actual engine.

Most large engine designers are now going in the direction of double cylinder, double-acting engines, both in this country—as shown in the Cockerill engine above referred to—and on the Continent in the Deutz engines. The reason for this is obvious. By using two double-acting cylinders, tandem, the power is doubled with small weight addition—little more than the addition of the extra cylinder—so that the crank is fully utilised and the weight for a given power materially reduced.

Fig. 30 is a cross section of the valve arrangement of the Deutz engine showing the governor gearing. In the ordinary large gas engine the hit-and-miss system has often been used, but in the more modern engines, the governing is more like that which is usual in a petrol engine, that is the charge is throttled. In the case illustrated the charge is throttled by the governor, *b*, operating the bell crank lever, *a*. When the rod, *c*, is lifted by means of the cam, *d*, it leaves the governor quite free to define the fulcrum of the lever, *e*. When the governor operates, the lever, *a*, is correspondingly moved, changing the position of the fulcrum of the lever, *e*. The consequence is, that though the cam lifts the rod at the same time, and opens the valve at the same time, the lift of the valve is varied, and in that way a very good governing is obtained.

ROTTERDAM AND HAMBURG.

Although the needs of the Port of London have been under Parliamentary consideration for many years past, and a Bill was framed upon the report of a Royal Commission, which urged urgency, and tabled, both last year and this, there is no likelihood of the necessary charges and expenditure being sanctioned during the lifetime of the present Parliament. Meantime, the authorities of Antwerp, as was recently explained in the *Journal*, have sactioned expenditure upon port improvements expected to reach five millions sterling, and two official reports just issued (Mr. Consul Turing's Report on the Trade of Rotterdam for 1904, No. 3391, Annual Series, and Sir William Ward's Report on the Trade of Hamburg, covering the same period, No. 3393, Annual Series), show the great progress that continues to be made in the shipping business of those two great seaports, Hamburg and Rotterdam.

Taking first the smaller of the two, Rotterdam, the most important event of last year connected with shipping interests was the completion of the fourth municipal dock, which was commenced in 1902, and ranks amongst the largest in Europe. Its length is 556 feet, with a breadth of 118 feet, and its lifting

capacity is 15,600 tons, while its total weight amounts to 6,500 tons. All the necessary appurtenances are worked by electricity, supplied by a station on the left bank of the river. Its total cost slightly exceeded £100,000. There are three other municipal docks in the port, whose lengths are respectively 360, 295, and 158 feet, and the fifth dock, owned by a private company, is capable of accommodating vessels of 7,500 tons. It is satisfactory to find that in 1904 the United Kingdom held its own at the port as compared with 1903. It is true that British shipping showed a decrease upon the year of 404,365 tons, and only represented 35 per cent. of the total of the port as against 39½ per cent. in the preceding year; but this diminution is solely due to the fact that the Harwich daily passenger steamers ceased running to Rotterdam, the voyage from the United Kingdom now terminating at the Hook of Holland, and hence their tonnage is excluded from the returns for Rotterdam. But for this circumstance the total entries of British ships would have exceeded those for 1903 by 40, and the tonnage would have shown an increase of 158,850 tons. But whilst the figures (making due allowance for the diversion of traffic as explained above) of 1904 are rather more favourable than those of its immediate predecessor, a comparison of the figures of the last ten years is disturbing. The percentage of the total tonnage of shipping entering the port of Rotterdam in 1895 under the British flag was 69; in 1900 it had fallen to 52; last year, as stated, it was 35. The decrease in the actual tonnage has been very slight—from 4,481,649 tons in 1895 to 4,419,373 tons in 1904—the significance is in the fact that the whole of the immense increase in the entries has gone to the continental rivals of the United Kingdom. Whilst the British tonnage entering the port has decreased by 62,276, the total entries in the same period have increased from 6,489,494 tons in 1895 to 12,603.550 tons in 1904. These figures indicate the volume of transmarine business, but a large additional amount of tonnage is represented by the arrival of 126,877 river craft with a capacity of 6,746,784 tons.

The commercial importance of a large seaport should not be altogether measured by, and does not chiefly depend upon the amount of sea-going tonnage frequenting such port, but rather upon the volume and value of the merchandise imported and exported. The following figures, taken from a report recently published by the Antwerp Chamber of Commerce, and quoted by Sir William Ward, would seem to show that the importance of Hamburg in this latter respect greatly exceeds that of Antwerp, and even that of London or Liverpool:—

	Value.	
	Total Imports 1902. Francs.	Total Exports 1902. Francs.
Hamburg	4,709,000,000	4,139,000,000
London	4,189,000,000	2,340,000,000
Liverpool	3,180,000 000	2,720,000,000
Antwerp	1,778,000,000	1,642,000,000

The aggregate number and tonnage of the seagoing ships of all nations entering the port of Hamburg in 1904 was the largest on record, the total registered tonnage having exceeded that of ships entering in 1903 by 455,000 tons. The aggregate number of sea-going ships which entered the port during the year was 14,859, and their total registered tonnage 9,611,732 tons. There was an increase of 177,288 tons register in the aggregate tonnage of the British vessels visiting the port as compared with 1903, the figures of last year both of the aggregate number and tonnage of the arrivals under the British flag having been the highest on record. Taking the last five years, there has been unbroken increase in the total annual tonnage of British ships entered, but it is to be noted that the increase in the total tonnage of German vessels entered during the same period has been greater. Of the 9,611,732 tonnage entering Hamburg in 1904, 3,353,147 was under the British flag, and 5,231,714 under the German.

Nothing, perhaps, in the history of shipping has been more remarkable than the rise and growth of the Hamburg-American Steamship Company. At the end of last year this company owned 310 sea and river-going vessels of all kinds, of an aggregate tonnage of 738,694 tons register. The aggregate tonnage of sea-going vessels alone was 612,299 tons register, and the aggregate tonnage building at the end of the year was 110,000 tons. The total number of passengers carried by the company in 1903 (the figures for 1904 are not yet available) was 304,346, and the quantity of cargo 4,800,554 cubic metres. The number of different lines maintained by the company, partly alone and partly in conjunction with other companies, increases steadily from year to year. At present the company carries on altogether 44 different services in various parts of the world, the most important being those to North America, to Mexico, the West Indies, the East and West coast of South America, and to Eastern Asia. The total profits realised in 1904 were £1,560,000, a result due on the one hand to the high prices paid by the Russian Government last year for several steamers sold by the company, and on the other hand to increased receipts on account of goods traffic on some lines, and also to the effects of the recently established system of insurance. That the company owes its success in great measure to its being constantly alive to the introduction of every possible modern improvement, not only as regards the construction, speed and safety of its ocean-going steamers, but also in regard to the accommodation and comfort of every description provided for passengers is well known. As an indication of the latter it may be mentioned that in some of the company's steamers passenger lifts have lately been constructed, the use of which, especially in rough weather, is certain to be much appreciated by passengers. Then a considerable space on board the company's tourist steamers is given to apparatus for hygenic gymnastics, and in some of the newest steamers restaurants are to

be found in order to offer passengers the option of taking their meals alone and at any time instead of being obliged to conform to the hitherto customary meal arrangements. Further, to attract passengers to use its steamers the company has recently taken over the entire business of a well-known German travelling agency, and intends establishing branch agencies in various countries.

Whether imports or exports are taken the United Kingdom is at the head of the list as far as Hamburg is concerned. Of the total imports by sea in 1904 amounting to no less than £125,203,520. £20,823,;0) came from the United Kingdom, the United States coming next with £19,753,229. It is noteworthy that India is third with £12,952,305. The chief articles of import to Hamburg, from India, are hides and skins, oleaginous seeds, rice, bone flour, myrabolans, cotton and cotton waste, jute and jute manufactures, indigo and shellac. And large as the sum named above as the value of imports from India, it is probable that the real value of the Indian produce which finds its way to Hamburg is much larger, for a considerable part of these goods is still handled by London houses, being shipped from India to London, the owner or consignee disposing of them to the port offering him the best price, receiving payment in time to meet the drafts drawn against them. But the steamer bringing the Indian produce discharges it in London whence it reaches the consuming port by another line, and the country of origin of the Indian goods when they reach Germany is then considered to be the United Kingdom, Belgium, the Netherlands, &c. In exports from Hamburg, as in imports to the port, the United Kingdom is first with £21,982,782, the United States taking only £13,029,056, and Germany coming third with £11,850,633. The exports to British India were only £3,025,755, to Australasia, £1,717,678, and to British North America they shrank to £476,194, owing to what may be called the tariff war. A proof of the growing development of the trade and general intercourse between Hamburg and oversea countries, and in particular of British colonies and possessions, is to be found in the fact that in the course of last year several large banks which do business more especially with India, the Far East, South Africa, and Australia have established branch offices at Hamburg.

Shipbuilding holds a prominent place at Hamburg, and has, in a greater degree even than most other industries, developed during the last 25 years, owing to the enterprise displayed in all shipping undertakings, and the remarkable strides made in Germany in naval architecture and engineering. There are at present 11 shipbuilding yards at Hamburg, employing altogether about 9,000 hands. In two of the yards the largest class of ocean-going passenger steamers or war vessels can be built. The steady growth of the aggregate tonnage visiting Hamburg necessitates constant improvements and additions to the existing arrangements provided for the accommodation, and the discharging and loading, of sea-going ships and numerous descriptions of river craft which frequent the Hamburg harbour. The average annual amount spent in dredging inside and outside the docks (in the river) is about £40,000. During the decade 1890 to 1900 the average quantity of material dredged was 1,140,000 cubic metres per annum. The most difficult bars in the river Elbe have been successively deepened during recent years from 13 to 14 feet to 24 feet 6 inches, and this result is now to be further increased to 32 feet 8 inches, at an estimated outlay of £312,000. The project of building a tunnel underneath the river at Hamburg for providing a more convenient connection between the principal portion of the town and the many shipbuilding yards and other industrial establishments on the south side of the Elbe appears likely to be carried out at an early date. A Frankfort firm has offered to undertake the work of constructing the tunnel for £425,000, and it is probable that this offer will be accepted.

WOODWORKERS' SCHOOLS IN GERMANY.

There appears to be a consensus of opinion that schools for woodworkers in Germany have proved a great blessing to the people, for besides bolstering up the industries of the country, they add greatly to the artistic pleasure and development of the people themselves. Many of the carved objects attain a very high degree of art, and the cabinet work is as wonderful almost as the creations in painting, bronze, and marble. The best proof of the value of these schools, and their efficiency, is found in the fostering attitude manifested by the various Governments, and the encouragement given by men in the trade. It is interesting to note that most of the schools appear to have been established at times when, through unfavourable tariff conditions or adverse economic developments, the woodworking industry had been thrown into exceptionally straitened circumstances. To relieve the stress, resort was had to education. The first independent school for woodworkers in Germany started about the year 1859. Before that time, carpenters, cabinetmakers, and other woodworkers had to content themselves with theoretical instruction offered in the schools for builders themselves, as well as in the industrial art schools, some of the trade schools, and the largest continuation schools. These schools frequently had special classes for carpenters, cabinet-makers, turners, and other professional woodworkers. Some guilds in the wood industry also maintained similar courses. The difficulty with this system of instruction was that too much emphasis was placed upon drawing, and scarcely any on the practical features of the woodworker's trade. According to a special report recently issued by the United States Department of Commerce and Labour, which has undertaken an inquiry into the question of industrial education in Germany, the first step to supply this want of practical instruction was

taken in 1859, when, through encouragement by the Bavarian Government, the first German school for woodworkers was established at Berchtesgaden, in the heart of the great forest domains of Bavaria, and in the seat of the leading branches of the wood industry—an industry which had been developing for centuries. This school originated as a branch of the drawing school of Berchtesgaden, which was established in 1840. In this school four different courses of work are given—a preparatory course, an evening course, a Sunday course, and a graduation course. The efficiency of these courses is greatly increased by the equipment of the school with a good library, large collections of plaster, wood, and other models, drawing charts, graphic productions of art and industry, and ancient wood carvings. An exhibition is held every year from June to September, when the last work of the students of the school is displayed. Articles so exhibited are for sale, and are disposed of through a reliable salesman supplied by the school. As regards fees, no charges are made for residents of the city of Berchtesgaden; non-residents pay twenty shillings for six months tuition. With the school at Berchtesgaden as a successful precedent, there soon developed a number of similar schools, some of which added courses for cabinetmaking and turning, in addition to the work in carving. One was established at Bischofsheim, and others at Partonkirchen, Oberammergau, Neuhammer, Kötsling, Fürth, and Furtwangen. The school at Fürth is especially important, and was established to meet the needs of the three great industries which flourish there—cabinetmaking, carving, and turning. Another important school is the one at Furtwangen. It has two departments—one for cabinetmaking, the other for carving—with three classes in each department. The curriculum for the department for cabinetmaking is divided into a practical and a theoretical part. Great emphasis is laid upon practical employment to fix the theoretical instruction given from day to day as the studies progress. Aside from the schools already enumerated, which are in Bavaria, there may be mentioned as among the most important, the school for turners and wood carvers at Leipzig, the school for wood carvers at Warmbrunn, Silesia, the school for cabinet making and wood carving at Flensburg, and the school for carpenters at Berlin. Numerous other schools of this class, of greater or lesser importance, are also found distributed here and there throughout the country, as the needs of industry have seemed to call for their establishment. Related to the school for wood carvers are the schools for basketmaking, such as are found at Heinsburg, in Prussia, and Lichtenfels, in Bavaria, which two institutions are among the leaders in this class. Schools for straw plaiting are to be found in different parts of the mountainous regions of Germany. The first was established in the Odenwald in 1845. Others soon followed in Saxony, and in the Black Forest, where the manufacture of straw hats has been carried on for centuries. It is interesting to note, in connection with the work of the woodworkers' schools, that the Tyrol, the Black Forest, Odenwald, and Thuringian forest lands are under very great obligations to them. Oberammergau owes a large part of its artistic powers to the development of its woodworkers in schools such as are here outlined. For a long time the Black Forest clock industry was threatened with extirpation. Competition with machine-made clocks was rapidly undermining the Black Forest factories. The schools of Furtwangen and in the Tyrol put it in the power of the Black Forest and the Tyrol people again to enter the world's markets, and to maintain a position therein. The beauty of the woodwork with which their clocks are now ornamented has made them great favourites in all parts of the world. Without the carved woodwork, it is a question whether the German or Swiss clock industries could continue to exist.

SANITATION IN BRITISH INDIA.

There are few matters in regard to which national ideas differ so radically as they do in regard to cleanliness. Men of one race, even of component nationalities in the same race, have very different standards. To define the differences which exist is not an easy matter, but it may perhaps be said that whereas the high caste Indian and the upper class Englishman has each a high personal standard, the one incomprehensible to the other, the essential difference lies in the recent English recognition of the necessity for a communal standard of cleanliness whose benefits shall not be personal but municipal or even national.

The Report on Sanitary Measures in India,* issued at the end of last year, is unknown even to many workers along these kindred paths in Great Britain. Its scope is a fairly wide one, and it deals with widely diverse concerns such as the health of the Army (British and Native), the terrible spread of plague, effects of vaccination, and general sanitary methods. Much of what is written therein is of purely medical interest, in particular that section which gives the history of the chief diseases. Of more general interest are the reports from the sanitary boards of the various provinces, whose activities are diverted into a number of channels. For instance, in Calcutta, the removing of clusters of native huts has been carried on as in preceding years. Progress was made in the extension of the filtered and unfiltered water supply. The length of the mains supplying filtered water is about 317¼ miles, and the total mileage of unfiltered water pipes 172¼ miles. The municipalities in the interior of Bengal spent £150,300, or 43·41 per cent. of their income on sanitary works during the 1901-2 financial year. The Bengal Sanitary Board has authorised

* No. Cd. 2298. Eyre and Spottiswoode. Price 1s. 6d.

the Muzaffarpur municipality to construct a septic tank. In the United Provinces of Agra and Oude, many improvements in various directions were carried out in the municipalities and smaller centres of population. Important drainage works are in course of construction at Allahabad, Cawnpore, Lucknow, Benares, Farrukhabad, and Aligarh, which "should prove of great utility in improving the public health of the country." In the Punjab the chief works which have been carried out were the Amritsar water works, the Simla sewerage extension works and drainage of the bazaars, the extension of the Lahore water works distribution system, and water and drainage works at Lyallpur and Ambala. The Delhi water works have been completed, and the city is now adequately supplied with pure water.

No large works were undertaken in the North-West Frontier Province, attention being mainly given to the cleaning and improving of wells and tanks. The water supply of Peshawar, Burma, and Bannu being extended or improved. From the Central Provinces, Assam, Burma, Madras, Bombay, and Berar similar reports are presented, and special note may be made of the report from Bombay. Good progress was made with the drainage work in Bombay city, but of the province as a whole, the Sanitary Commissioner says that "real sanitary progress has been at a standstill for some years past, on account of the plague epidemic, which shows no signs of abatement." No progress was made in the introduction of the Village Sanitation Act, owing to the prevalence of plague and famine, which have absorbed the attention of district officers in recent years.

The book as a whole is full of material of medical and social interest, giving, as it does, details not only of pathological matters, but also of matters of municipal administration.

THE FRUIT INDUSTRY.

The Report of the Departmental Committee appointed by the Board of Agriculture and Fisheries to inquire into and report upon the Fruit Industry of Great Britain, is a very able statement of the position and prospects of that industry. The evidence collected by the committee is of great value, and the conclusions drawn from it are likely to meet with general acceptance. In the selection of witnesses, the committee endeavoured to procure thoroughly representative men by inviting various corporate bodies and local authorities to delegate one of their members to give evidence. Besides hearing evidence, the committee visited some of the chief fruit-growing districts in England, and they submit a series of recommendations which will, no doubt, result in certain changes in existing law and practice. According to official statistics the total acreage under orchards in 1904 was 243,008 acres, of which 236,705 were in England, 2,490 in Scotland, and 3,813 in Wales. These figures refer to orchards only, not to small fruit, though in many cases there would be small fruit under the orchard trees. Taking the figures by counties it will be found that six counties comprise three-fifths of the orchard acreage of Great Britain—namely, Kent with 29,055 acres, Hertfordshire with 28,042 acres, Devonshire with 27,346 acres, Somersetshire with 25,265 acres, Worcestershire with 22,387 acres, Gloucestershire with 20,385 acres. Hertfordshire has the largest acreage in proportion to its size of any county, no less than six per cent. of the cultivated land being orchard; Worcester follows next with 5·4 per cent., and Kent stands third with 3·7 per cent.

Turning next to small fruit, the total acreage in 1904 was 77,947 acres, 70,612 acres being in England, 6,072 in Scotland, and 1,263 in Wales. In this case one county—namely, Kent—is far ahead of any other, having no less than 22,549 acres. Next comes Middlesex with 4,700 acres; then Worcestershire with 4 546 acres; then Cambridgeshire with 4,403 acres; then Norfolk with 4,030 acres; then Hampshire with 2,472 acres; then Essex with 2,061. No other county reaches 2,000 acres of small fruit; but whilst this acreage represents only a small proportion of the cultivated land in Great Britain, the fruit industry appears to be a very progressive industry. Taking orchards, there has been an increase from 148,221 acres in 1873 to 243,008 acres in 1904, or 63·9 per cent. in 31 years. Taking small fruit, there has been an increase from 69.792 acres in 1897 to 77,947 acres in 1904, or 11·7 per cent. in seven years. With this remarkable growth it is instructive to compare the decline of every other crop in Great Britain. There has been a decrease in the acreage of wheat from 2,564,237 acres in 1888 to 1,375,284 acres in 1904, or 46·3 per cent. in 16 years; a decrease in the acreage of all corn crops from 8,187,758 acres in 1888 to 6,953,034 acres in 1904, or 15 per cent. in 16 years; a decrease in green crops from 3,471,861 acres in 1888 to 3,036,026 acres in 1904, or 12·5 per cent. in 16 years; a decrease in hops from 58,494 acres in 1888 to 47,799 acres in 1904, or 18·2 per cent. in 16 years.

What is the explanation of this remarkable increase in fruit cultivation? It is to be found in the extraordinary growth of the taste for fruit on the part of the public. Fruit is becoming more and more a regular article of food for all classes, and, except in special years of glut, the home supply has not kept pace with the demand. Nor is it only the consumption of fresh fruit which has largely increased. There is a great and growing demand for jam, preserved fruits, and even cider. As regards cider, there was a falling off for many years both in the public taste for it and in its manufacture, due largely to the deterioration of the great vintage orchards in the West of England which, planted in the seventeenth century, had seldom been replenished. In the last ten years, however, renewed attention had been paid to the industry, a considerable amount of planting has taken

place of cider varieties of apples, especially in Herefordshire, and organised efforts have been made, with considerable success, to revive the trade.

That the extension of the fruit industry is a benefit to the country, and should be encouraged by all proper means, is demonstrable. As the committee point out, fruit has taken the place of wheat where it has been found impossible to make wheat pay, and the profits from fruit growing, taking one year with another, are far greater than those from ordinary farming. The committee say that when visiting the Evesham district they saw land which was let a few years ago for ordinary agricultural purposes at not more than £1 an acre, and is now fetching £6 an acre as a fruit plantation. Evidence of similar advancement of value was given the committee from Middlesex. Open land in the county is to be found for which the rent is £3 an acre, while on the other side of the hedge there is similar land for which the tenant is paying £10 an acre, simply because it is under fruit. And of course with the advancement of rent comes an increase in selling value. Again, the planting of fruit means great additional employment of labour in country districts. A fruit plantation employs far more labour than any other crop with the possible exception of hops. If the evidence of Mr. Wood, of Swanley, is to be accepted, and he is a grower not only of fruit on a very large scale but also of hops, fifty acres of fruit land properly cultivated costs more money in labour than 1,000 acres of ordinary corn land, and Mr. Wood put the average labour bill down at £25 an acre per annum both in the case of fruit and hops. The committee believe that "no better means can be devised for bringing people back to the land than an extension of the fruit industry where it can be done profitably. Nor is this all. It should be remembered that besides the regular labour employed all through the year a great amount of extra labour is required during the picking season which, in the case of fruit, lasts for three months, and this labour is obtained chiefly from London and other large towns and industrial centres, thus providing a special opportunity for many of the workers in other places of enjoying a most healthful and profitable change into the country." There is abundance of land where fruit growing might be profitably undertaken.

Not that it is all plain sailing. The industry has to reckon with difficulties and drawbacks many of them of a serious character. The committee summarise these disadvantages and some of them may be given here. (1) There is insufficiency of knowledge as to the right kinds and varieties of fruit to plant, the character of the soil, the effect of manuring, pruning, and general treatment, diseases and insect pests, packing and grading; (2) it is difficult to obtain land for the cultivation of fruit with equitable adjustment of the respective rights of landlord and tenant; (3) there is often unfair valuation of fruit holdings for the purposes of local rates and imperial taxation; (4) the fruit grower has cause of complaint against the railway companies, excessive rates, preferential rates, unpunctual deliveries, bad handling, pilfering, inadequate service, and refusal to pay claims; (5) foreign competition and tariffs hostile to British fruit; (6) indifferent inspection of foreign fruit; (7) the difficulty of obtaining labour in country districts; (8) the insufficiency of markets and other market grievances; (9) the ravages of birds. The committee deal with all these complaints and for the most part reach the conclusion that they are well founded. Readers are referred to the report itself for detailed reference to these matters. Here may be given the chief recommendations and suggestions made by the committee.

They recommend that a special sub-department of the Board of Agriculture and Fisheries be established to deal with matters connected with the fruit industry, and that there be two branches of such department, (*a*) a bureau of information, (*b*) an experimental fruit farm: that horticulture be taught in elementary schools in country districts, and that such schools should have school gardens attached wherever possible; that the Market Gardeners' Compensation Act be amended by making Section 4 retrospective; that when a tenant gives notice to quit he shall not be entitled to receive compensation unless he presents to the landlord a successor who is willing to take over the holding at the same rent; that in the event of his so doing, and the landlord accepting his nominee, the compensation be paid directly by the new tenant to the old tenant, but that the landlord have the right to refuse to accept the outgoer's nominee, in which case he must pay compensation to the outgoer under the provisions of the existing law; that the State be empowered to lend money to landowners who have fruit on their estates, subject to certain conditions, for the purpose of supplying the ready money required for the payment of compensation at the determination of a tenancy; that a Bill should be passed for facilitating the purchase of small holdings by tenants somewhat on the lines of Mr. Jesse Collings' Bill of last session; that in the assessing of agricultural holdings for local rates, the assessment should not be raised by reason of the planting of fruit for a period of five years after the planting in the case of small fruit, or seven years in the case of mixed plantations, and twelve years in the case of orchards; that a more simple and uniform system of rates for fruit be introduced by the railway companies, and that they should make greater efforts for ensuring the prompt delivery of perishable fruit; that jams made wholly, or in part, from foreign fruit be labelled, and the Government should undertake the inspection of imported fruit and fruit pulp at the ports of entry; that the present by-laws for building in country districts be modified so as to allow of the cheaper construction of cottages; that fruit growers should pay more attention to the careful packing and grading of better class fruit, and the selection of the right kinds of fruit to plant according to the soil, and to the importance of cultivating fewer varieties, especially of apples. It will be seen

that the recommendations of the committee, of which only some of the most important are named above, are many and various. Perhaps one of the most striking facts brought out by the evidence taken by the committee is the growth amongst fruit growers of what may be roughly called the "Ulster" custom. Under the provisions of the Market Gardeners' Compensation Acts, a tenant of a holding, which it is agreed in writing shall be let or treated as a market garden, may plant fruit, and erect the necessary buildings without having first to obtain the consent of his landlord, and at the end of his tenancy is then entitled to compensation which often amounts to a very large sum an acre. In the Evesham district, it is the almost invariable custom for the outgoing tenant to find an incoming tenant who buys him out, the landlord neither paying nor receiving any money, and rarely objecting to the outgoing tenant's nominee, the fact that he is able to pay out his predecessor being a sufficient guarantee of his financial position. This custom is not easily distinguishable from "tenant right" in Ireland, which successive Governments have sought to abolish by giving the tenants great facilities for purchase of the fee simple.

IRON ORE DEPOSITS IN FOREIGN COUNTRIES.

The reports on iron ore deposits in foreign countries compiled at the Board of Trade from information collected by His Majesty's Diplomatic and Consular officers, and just issued, have been made in response to a request of the British Iron Trade Association. The Association asked Lord Lansdowne to obtain information as to the extent and character of iron ore supplies in foreign countries, and the particulars sought were described in a series of questions which the officials to whom they were addressed were desired to answer "directly and precisely." The result is a bulky volume containing much that should be of use to the interests concerned.

The two greatest coal-producing areas of the world are those to be found in the State of Pennsylvania and the province of Shansi in China. The area of Pennsylvania is 43,960 square miles, containing 20,000 of coal land. The area of Shansi is 55,000 square miles, and Professor Dana thinks it probable that "it will take the palm from Pennsylvania by a considerably more favourable proportion." In 1891 the only mine in Pennsylvania which produced as much as 100,000 tons per annum was the Cornwall mine from which magnetic iron supplies were obtained. The State of Pennsylvania in 1890 made 48 per cent. of the pig iron production of the United States, declined to 46·2 per cent. in 1900, and further dropped to 45·5 per cent. in 1902. These declines, however, were almost entirely confined to the eastern part of Pennsylvania, whilst in the western part there have been almost proportionately large advances, but lake ores were used entirely. In Shansi the coal can be extracted with greater ease and cheapness, but this great coal and iron region labours under two serious disadvantages. Firstly, it is situated a distance away from the coast, and from rivers that are fit for other navigation than by small Chinese boats; and, secondly, the whole of the coal formation rests, as it were, on a platform raised some thousands of feet above the adjoining plain. The steep ascent from the latter offers great difficulties to the construction of a railway, which will be the only means of ever bringing to account the mineral wealth of Shansi.

At the request of the Governor of Utah, Mr. A. C. Milner, of Salt Lake City, drew up a valuable report on the coal area of that State, and forwarded it to the Consul-General for the purposes of the present compilation (page 244). The iron deposits are situated in South-Western Utah, in Iron Mountain and Iron Springs districts, which are about 22 miles south-east of the Oregon Short Line railroad. These deposits cover an area of 15 miles long by about three miles wide, the ore showing on the surface at three different points. It is principally a soft red and brown hematite, which can be handled easily by steam shovel, except where blow cuts occur, which are hard and magnetic. Hundreds of acres will require only from one to three feet of stripping. Ore can be stripped, mined, and put on cars for 15 cent. per short ton (2,000 lbs.). Various experts who have made examination of these properties state that this is the largest surface of iron ore in the world. The tonnage in sight is so great that it is very difficult to state what it is, but the experts have made estimates from 100,000,000 to 500,000,000 short tons. About 25 per cent. of the ore is Bessemer, the balance being basic. The ore runs an average of about 60 per cent. metallic iron. The average in silica is about 7 per cent. The limestone adjacent to the iron has all proper fluxing qualifications necessary in furnace work. The iron-fields are 273 miles from Salt Lake City, and 445 miles by Clark Road Survey from San Pedro Harbour, which is the Pacific Coast terminus of the Clark Road.

The United Kingdom relies largely upon Spain for the supply of iron ores, and from 70 to 80 per cent. of the shipments from the three provinces of Viscaya, Guipuzcoa, and Santander are consigned to this country. Spain does all in her power to encourage the exploitation of her mineral wealth by foreigners, who are on a complete equality with natives in taking out claims for mines. The Bilbao ores are sold on a 50 per cent. basis of metallic iron, and in many cases a proportion of inferior ores is shipped with those of good quality in order to keep the average analysis to the above percentage. Very much depends, naturally, in such cases on the care used in the mining and picking, as well as on the state of the weather during extraction and shipment, a most important consideration. The qualities of ore presumed to be still in deposit were put down in 1897 at forty or fifty million tons in Biscay, but over thirty million

tons have been worked out since then. The indications of exhaustion, however, appear, according to Mr. Consul Ward, to be still similar to those on which calculations were based eight years ago, judging from the fact that the exploitations and shipments still nearly keep up to the level of previous years, *i.e.*, at the rate of about four or five million tons annually. There is little doubt, in the Consul's opinion, that new mines as well as old ones make up among them for the lesser quantities produced by the failing or already exhausted ones. Engineering is an exact science, but how far experts in it may be trusted when they take to divination no one can safely say. The latest expert opinion puts the available iron ore in the actual mining district of Bilbao at 50,000,000 tons.

Amongst what may be called undeveloped countries Abyssinia is believed to be exceptionally rich in iron ore, but under present circumstances, as Mr. Clerk points out, the difficulties of obtaining a concession on fair terms, the enormous cost of importing machinery and exporting the ore, and the comparatively small demand for iron in the country itself, would entail a heavy deficit for many years on any company that undertook to work the mines. Moreover prospectors of various nationalities have visited nearly the whole country, and the mineral rights of those districts which show most chance of paying have already been taken up by groups of concessionaires. All land belongs to the Abyssinian Government, and no proprietary rights would be sold. Working rights for a limited number of years might be obtained. All working is very primitive: no shipments have ever been made. If, says Mr. Clerk, the Emperor Menelik supports the mining company, the chief difficulty would be removed. But there would probably be, especially at first, endless minor difficulties, and such a company must remember that it is entirely dependent on the caprice of the Government of the country. Only a competent mining engineer could give a proper estimate of the prospects of iron mining in the regions of Abyssinia not already given to prospectors or concessionaires. "My own untechnical opinion," writes Mr. Clerk, "is that until transport is cheaper and the country more educated, to attempt to work the iron here would be a dead loss; the only reason for applying for a concession would be to forestall others. To do so a capitalist, or a syndicate, must be prepared to lose money for many years in the faint hope of an eventual profit."

In 1902 there were working in Sweden 332 mines, which yielded an aggregate of 2,896,208 tons of iron ore (viz., 2,615,533 tons of magnetite and 280,675 tons hematite ore), valued at £798,181. Labour-saving machinery is utilised as much as possible. Rock-boring machines, either pneumatic or electrical, are in use, the electric power for them and all other requirements being generated at the mines and transmitted from a power-station in the neighbourhood. In no civilised country is there less willingness to encourage foreigners to engage in mining operations. A foreigner is not allowed to hold either land nor mines, or, since 1895, to act as a director o public companies in Sweden without special permission of the King. In the Articles of Association of the body controlling the business of export companies it is agreed that the shares cannot be registered in the name of a foreigner. Mining properties are occasionally offered for sale to foreigners, but such proposals, says Mr. Consul McGregor, should be treated with the greatest caution on account of the difficulty of obtaining the necessary title. In Russia the largest and most important deposits of iron ore are to be found in the Krivoi Rog region. The ore bed lies along the rivers Saksagan, Ingulez, and Jeltaya, in the form of a narrow strip, for a distance of about 40 miles. When the ore was first worked the rent of the land was only about 4s. per acre, but with the development of the industry rents rapidly rose, and towards the end of the nineties 1s. 4d. to 2s. per ton was freely paid, eventually reaching 4s. per ton, in some instances being coupled with guarantees of minimum annual payments of £8,000 to £12,000. The latter works out at about £75 per acre per annum. Of the total output of iron ore in South Russia, 94 per cent. falls to the share of Krivoi Rog, 3·5 per cent. to Kertch, and the remaining 2·5 per cent. to Donetz ores. Under an Imperial decree of May, 1898, all foreigners are prohibited from acquiring by purchase, or otherwise, in certain districts of the Caucasus, any lands situated outside the limits of towns and settlements, except under special certificates granted, in each separate case, by the Governor-General of the Caucasus.

Iron ore is said to exist in almost every part of Madagascar, but it is worked only in the Central Provinces. The quality is poor. As coal has not been found in the island as yet, and roads are almost unknown, the natives are obliged to remain in the vicinity of forests where the iron ore is smelted by rudimentary means. Transport to the nearest port, Andevorando, would co t rom £10 to £14 per ton. In the Philippine Islands, extensive deposits of iron ore are known to exist, but their development must be preceded by the development of the coalfields. There are now some 1,200 prospectors and practical miners scattered through the different islands of the Archipelago, most of them American. So far, no European trade in iron ore has been carried on in German East Africa, but there are three localities which, it is thought, might be exploited with satisfactory results. In Morocco, there are numerous iron ore deposits, but down to the present all prospectors have been regarded with great suspicion, and consequently no scientific investigations have been possible. The liberality of the Spanish law —which does not seem to have been altered since the war—in Cuba is noticeable. No export tax has ever been paid, and import taxes on materials have been light, and at times *nil*. Nor has the man who located the mine had to pay anything beyond a

moderate fee for measuring and registering, and once in his possession he has not been asked to pay any further tax however long the mine might remain in his possession without his working it.

LIQUID FUEL FOR STEAMERS.

Liquid fuel is now largely used by the Dutch steamers of the Koninklyke Paketvaart Maalschappij (Royal Packet Company) plying between the different islands of the Netherlands Indian Archipelago. It is residue from the petroleum wells in Netherlands, India, the greater part being from the Asiatic Petroleum Company's wells in Borneo. The total consumption of the liquid fuel by the Royal Packet Company's steamers, according to the American Consul at Batavia, amounted to 11,700 tons in 1902, and 16,500 tons in 1903, while in 1904, the estimated consumption was 26,000 tons. The company has contracted for a supply for the years, 1905 to 1907, with the Asiatic Petroleum Company, to the extent of 32,000 tons per annum. The ton is calculated at about 265 gallons. The fuel sells at about thirty-two shillings per ton, but it is understood no such price is paid by the Royal Packet Company when contracting for large quantities. At the present time, there are seventeen of the company's steamers using liquid fuel, and it is found much more economical than coal, better for the boilers, cleaner in every way, and fewer men are required to work the furnaces.

Credit is given to the Superintendent-Engineer of the Royal Packet Company, for inventing a system of injecting the liquid fuel into the furnaces of the steam boilers. The fuel is brought under a pressure of from ten to twenty pounds to the square inch and evaporated by a somewhat modified "Korting's" burner, without use of steam. This apparatus works very satisfactorily, without noise and without the loss of fresh water. Formerly the liquid fuel was injected into the furnaces by means of a steam jet, making very much noise, a great inconvenience, annoying to the passengers and causing the loss of much fresh water in the form of steam. A suitable furnace arrangement guarantees proper and perfect burning of the fuel, so that very little smoke escapes from the funnel, steam is kept regularly at the same pressure during the voyage, and the boiler is kept as a uniform temperature, thus preventing much trouble from leakage and other damage. Liquid fuel was first used by the Royal Packet Company in 1898, and as it has been found satisfactory, all new ships built in the Netherlands have been furnished with proper boilers for the use of this fuel, and many of the older boats have had the necessary change made. It is therefore, it is said, only a question of time, when all the steamers of the company will use liquid fuel.

OBITUARY.

JOHN PRATT.—The death at Chattanooga of Mr. John Pratt, the inventor of a very early form of the typewriter, has recently been announced. In 1867, Mr. Pratt read a paper before the Society, "On a Machine for Typewriting," and exhibited one of the apparatus invented by himself. His paper will be found in the number for May 3rd, 1867. The apparatus is described in full detail in his paper, and a shorter description is given in the *Journal* for the 18th of February, 1876, drawn up from one of Mr. Pratt's machines which was then in the possession of the Society. The machine was not at that time in working order, some of the parts having been broken, but it was still capable of producing work.

The types are all fitted on the face of a small plate, about three-quarters of an inch square. This is supported vertically before a frame carrying the paper by an arrangement of levers capable of giving it both a vertical and a horizontal motion. By a proper combination of the two movements, the plate can be shifted into any position, and consequently any type required can be brought opposite the point where the impression is taken. As this is done, the same mechanism which moves the plate sets in motion a small hammer, which strikes on the paper on the opposite side to the plate, and strikes the paper against the type, thus producing an impression. Carbon paper is, of course, used in this as in the other machines above mentioned, and therefore several copies can be taken. In order to limit the number of keys required to operate the levers for shifting the type-plate, the inventor had one set of keys for giving the vertical movements, and another for giving the horizontal movements. Thus, for each letter it was required to move two keys, but as each key of one set could be used with each key of the other set, a much smaller number of keys was required than if one key were required for every letter. It may make it appear clearer to say that the depression of one key brought into position the vertical line containing the type required, this depression of the other, the horizontal line containing the same type, and consequently the intersection of the two lines, where the special letter needed was to be found, was brought into the proper place for the impression. Then, if K be the number of keys, T the number of types, it is obvious that $K = 2\sqrt{T}$, *e.g.*, for 64 types 16 keys would be wanted. The paper was carried in a small frame, traversed after each letter by a rachet-wheel and pall. At the end of a line the frame was raised by a rack worked by a separate key, and at the same time thrown back to the proper side of the machine for commencing a fresh line.

Mr. Pratt's machine was patented in Great Britain and in America, and there is still in the Patent Office at Washington a typewritten letter which accompanied the model deposited with his application for a patent.

He was born at Unionville, South Carolina, in 1831, and for a good many years he practised as a lawyer and a journalist in the Southern States. At the time of his reading the paper he was resident in Alabama. He afterwards lived in Brooklyn, but he had resided in Chattanooga some two years before his death. It was only last year that a renewed communication with him led to his becoming a member of the Society, to which he had contributed a paper, now of considerable historic value, nearly forty years before.

GENERAL NOTES.

AMERICAN BEET SUGAR.—In 1897 the State of New York commenced the manufacture of beet sugar, but the experiment has not been a successful one. In that year a law was passed for the promotion of the culture of sugar beet, a bounty of not more than one cent per lb. being given for sugar made in accordance with the requirements, and about £5,000 was appropriated for the purpose. Factories were to obtain a distributive share of this appropriation, provided that all the beets they used were grown in the State of New York, that they did not grow their own beets but paid not less than £1 per ton for them, and that the sugar they produced contained not less than 90 per cent. of crystallised sugar. The policy declared at the time was to make direct appropriations from the State for a successive period of not less than five years in aid of the permanent establishment of the beet-sugar industry in the State. The bounty was first paid at a maximum of ½d. per lb., and the appropriations increased from £5,000 in 1897 to £20,000 in 1901, but in the following year the appropriation was reduced to £10,000, and the bounty was also cut down to ¼d. per lb., at which figure it remains. In 1897 a factory was set up at Orme, New York, the machinery being imported from Canada; in 1898 a second factory was established at Binghamton, and in 1899 a third factory at Lyons. These, says Consul-General Sir P. Sanderson, from whose report (No. 3353, Annual Series) these facts are taken, seemed to do well at first, and the central part of the State appeared to be well adapted to the cultivation of the sugar beet, but the industry made little progress. In 1900 the factory first established went into liquidation, the causes given being insufficiency of capital and difficulty in obtaining beets, and in 1904 the Binghamton factory removed to the State of Idaho, so that at the present time there is only one factory in operation in the State of New York. The approximate amount of beet sugar manufactured in the State in late years has been in 1899, 3,600 tons; in 1900, 6,000 tons; 1901, 4,050 tons; 1902, 2,800 tons; 1903, 4,400 tons; 1904, 3,200 tons; the ton in each case being reckoned at 2,240 lbs.

SAMOA PRODUCTS.—In his report upon the trade of Samoa for 1904 (3380 Annual Series), Mr. Acting Vice-Consul Trood speaks of the profits to be derived from cacao and cocoanut plantations. The cacao plantations, small and large, are all doing well, but a good crop is not to be got in less time than five years from the time of planting, and meantime the trees require much care and attention. On this account small proprietors are at a disadvantage since they are not only unable to acquire labour as easily as the large plantations, but often find it difficult to raise money to pay for labour when they get it. Consequently in this case trees which would produc heavy crops in five years' growth on the large holdings, bring little return to them for seven or eight years. Not less than £2,500 are required to start a cacao plantation, the cost per acre from clearing the land to the gathering in of the first crop being put at £25 to £30. But a cacao plantation pays handsomely once it gets into full bearing. Mr. Trood instances a small plantation 20 miles from Apia to the westward — started four years ago — which yielded its proprietor at the end of 1904 6,000 lbs. of cocoa from eight acres, worth in Apia, 6d. per lb. As regards cocoa plantations, the trees in Samoa scarcely ever suffer from disease, and not one tree in a thousand is blown down by a hurricane, while however severe may have been the cyclone the trees are not affected by it for more than 21 months afterwards, and then yield a larger crop of cocoanuts than they did before the gale. They offer further advantages as regards the pasturing of cattle under them which can be turned in amongst the trees as soon as they are of eight years' growth. The cost of making a plantation of, say, 200 acres of cocoanuts (and no plantation of a smaller size, Mr. Trood says, would bring in even a moderate income) cannot be reckoned at less than £30 to £40 per acre.

THE TRADE OF NORWAY.—Probably Christiania is the only European capital whose population actually declined in 1904, and whose assessment was lower than in 1903. The population of the Norwegian capital lessened by about 1,303 souls, and there was a decrease in the assessment of 5·15 per cent. on property, 4·26 on incomes, 6·05 on taxable income, and 1·10 on trade taxes. These figures, however, represent only the original assessment, which is subject to many reductions amounting to as much as 16 per cent. of the assessed amount of the trade tax for the year. In his report just issued (No. 3425, Annual Series), the Consul-General, Lord Melville, gives particulars of the number of commercial travellers' licenses issued by the Christiania police authorities in 1904. They numbered all told 1,401, including 354 licenses issued in other places and visèd in Christiania. Of these 1,401 no fewer than 803 were German and only 132 British, and this notwithstanding that the number of German residents trading in the country is far more numerous than the British. One would have supposed, says Lord Melville, that the greater number of Germans engaged in business up and down the country would have rendered so large a number of travellers from the Mother Country unnecessary. The inference seems to be that a large number engaged in business in the country is not all sufficient. Emissaries must be sent that no chance may be lost of finding a market, and personal solicitation is more effective than letter and catalogue. Lord Melville says that "on the whole" British goods find favour "if the price is in accordance with the national means," but "more push is required."

NOTICES.

EXAMINATIONS.

The results of the Advanced Examinations (Stage III.) have just been published, and copies sent to all centres for distribution to candidates.

The results of the Intermediate Examinations (Stage II.) will be published about the middle of August, and those of the Elementary (Stage I.) towards the end of that month or early in September.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

INTERNAL COMBUSTION ENGINES.

By Dugald Clerk, M.Inst.C.E.

Lecture IV.—Delivered March 6th, 1905.

SYLLABUS.

Future Developments.—Petrol engines—Suction producers—Blast furnace gas—Producer gas in power stations—Air supercompression—Exhaust supercompression—Marine gas and oil engines—Line of advance.

No lectures on internal combustion motors would be complete without some reference to petrol motors. Gas engineers have learned much from the petrol motor, and from the very able Continental and English engineers who have devoted themselves to this subject. They have produced most serviceable and powerful little motors, running at speeds of rotation which would have been deemed commercially impossible even ten years back. Among these motors, as among large engines, the battle of the types continues, and ultimately each purpose will develop its standard type. Indeed, at present petrol motors are rapidly approximating to standard conditions. This was very noticeable at the recent exhibition at Olympia. Most of the engines were of the inverted vertical type.* Even Lanchester, the most original of all inventors in this field, has at last conformed to the general trend. Many excellent horizontal engines, however, are in use; and a test was recently made for me at the Wolseley Works, Birmingham, on a 6 horse-power horizontal Wolseley engine, by my colleague, Mr. M. A. Adam, B.Sc. In this test there was taken brake power, petrol consumption, and the calorific value of the petrol used. Indicator diagrams were also obtained by the Hospitalier Carpentier instrument. The indicated efficiency found in this test was 19 per cent., the ideal efficiency for an engine having the same compression, *i.e.*, $\frac{1}{4}$, being 43 per cent.

I must, however, leave the subject of petrol motors to discuss three important developments of the gas engine industry, viz., suction producers, blast furnace gas, and producer gas distributed from central stations.

The suction producer is already well established, and many hundreds of installations have been set to work during the past year, and are now operating with great success. The advance in the suction producer promises to be even more rapid, and I think that very much power will thus be developed and supplied at an economical rate. Blast furnace gas also offers a very important source of power: at least a million horse-power can be continually produced from the blast furnaces which are at present at work in this country. This enormous force is as yet hardly touched. There is actually about a million horse-power in the shape of gas going practically to waste from the iron furnaces of the country, and

* Lantern slides and photographs illustrating the following were shown:—Siddeley petrol motor; Wolseley petrol motor; Walthamstow Electric Lighting Station producer plant; Mond Gas Company's Staffordshire Station; Cockerill engine working with Mond gas at Messrs. Richardson, Westgarth and Co.'s Works, Middlesborough; Napier motor boats; marine motors and boats built by Messrs. Thornycroft.

that is one of the great developments of the future which is being tackled, and the difficulties have been overcome to a certain extent. Much remains to be done. Central stations for producing and distributing fuel gas are also in prospect, and one large installation will be started within a few weeks.

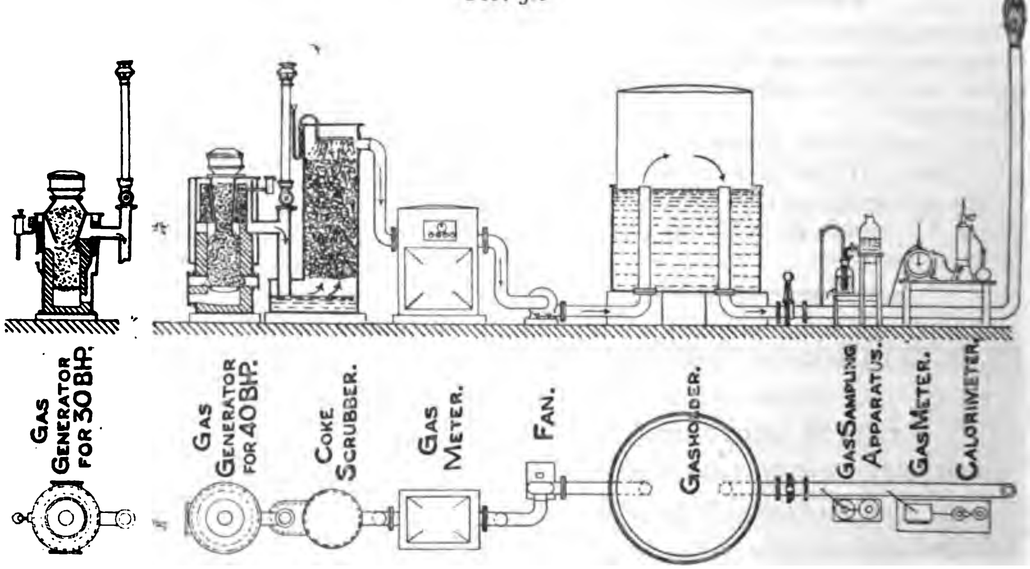
I will shortly consider these three matters in turn. Beginning with the suction producer, Fig. 31 shows a vertical section and plan of the Dowson suction producer arranged for an efficiency test, a separate generator being shown on the left. In the original Dowson pressure producer a fire is lit within a firebrick casing, and a mixture of air and steam is blown under the grate and into the fire by means of a steam jet from a steam boiler, the steam jet inducing an air current. The air and steam mixed pass through the anthracite and decompose the fuel; that is to say the steam is decomposed and the carbon combined with the oxygen of the water and the oxygen of the air, forming carbonic oxide gas, as represented by the formulæ—

$$C + O = CO \quad .. \quad .. \qquad (1)$$

$$\text{and } C + H_2O = H_2 + CO \; .. \qquad (2)$$

Steam cannot be decomposed without the addition of heat, but steam in the presence of red-hot carbon, or a little more than red-hot carbon, will decompose, and carbonic oxide and hydrogen are obtained, but this action absorbs heat. The combustion of the carbon as set out in the first equation gives out heat which is utilised according to the second equation to break up the steam. The function of any producer, however, of the pressure or suction type is to utilise the heat from the combustion as much as possible so as to give, instead of the solid carbon in the anthracite, a mixture of gaseous fuel, carbonic oxide, and hydrogen, with diluting nitrogen, in order to give a fuel suitable for introduction into the gas engine or internal combustion cylinder. Theoretically, that transformation from the solid carbon by means of air and steam can be made without loss, but practically there is always some loss. If it were possible just to keep the furnace at the temperature at which all the heat that left the furnace would be taken up for heating the entering steam, it would be possible to get a reaction which would give 100 per cent. of the heat in the form of cold gaseous fuel ready for the gas engine; but there is always a ratio of imperfection or inefficiency, and in the pressure producer the usual proportion of heat converted into gas ready for the engine is about 75 per cent. to 80 per cent.; that is, 100 heat units given from solid anthracite give 75 or 80 units in the form of carbonic oxide and hydrogen in the pressure plant; 75 per cent. to 80 per cent. is a better result than is obtained in most steam boilers; but in the suction gas plant even better results can be got. My colleague, Mr. Adam,

FIG. 31.



DOWSON SUCTION PLANT.

made a test of a Dowson suction plant some months ago, with the object of finding out the exact number of heat units of the fuel converted into gas which was ready for use in the engine, and he found, as the result of nearly a fortnight's testing, that every 100 heat units put into the suction producer at Dowson's Works gave out a matter of about 90 heat units, in the form of gas suitable for use in the engine. In the pressure producers, a steam boiler or a blower has to be used, and water has to be evaporated to go in with the air, and to decompose the steam and air by means of incandescent fuel. In the suction producer all that is done away with. The producer is started by a small fan worked by hand for about ten minutes, the whole of the mass of anthracite becoming incandescent. Water is supplied continuously, and is vaporised and drawn in by the air passing through the producer. At the start the hand fan is blowing gas right through the apparatus, and to a cock near the gas engine to make sure that the engine is getting a proper gas supply. When the gas becomes rich enough, the fan is stopped, and the engine is started in any usual way, and then begins to draw gas through the producer in exactly the quantity required for its operation, no fans or blower being required. The mixture of steam and air sucked in through the producer gives carbonic oxide, hydrogen, and a little light hydrocarbon. The gas formed, with nitrogen from the air, goes to the scrubber, where it passes through coke over which a constant stream of water is pumped. The gas passes through a little sawdust to take any final tar out before it reaches the engine. This arrangement is found to be exceedingly effective, and it is coming into use very largely all over the world, because it has a very high efficiency, and there is no danger attached to it. There is no danger of poisonous or inflammable gas. The gas in the producer is in the pipes, and always at a pressure a little below atmosphere, because it is being sucked into the engine by the motion of the engine itself, giving an extremely handy and simple producer in a form that anyone can work, however unskilled. The producer may be placed in comparatively confined spaces, and without any danger of gas poisoning, which was one of the dangers of pressure producers, and consequently, all over the world these suction producers are coming into use. Taking the ordinary price of anthracite delivered—in the tests which Mr. Adam made it was 24s. a ton—and taking a National engine of 40 horse-power, the price works out for 1 horse-power hour at rather under one-ninth of a penny. That is an exceedingly economical result, which practically no steam engine with anything like the same dimensions can attain. Speaking now of the future, although many of these producers are working at the present time, yet the future development is likely to be enormous; the competition with coal gas will be very keen; and the competition with other kinds of power will also be very keen. Producers are now made in this country by the Dowson Company in series of from 10 to 200 horse-power, and, in a very short time, producers will be made of that type up to 2,000 or 3,000 horse-power. If necessary, Mr. Dowson tells me, he is in a position to build 500 horse-power suction producers if they are required.

A very large installation of these producers is now working at the Electric Lighting Station at Walthamstow. The installation consists of a number of generators, each capable of developing enough gas for 375 horse-power, and Mr. Dowson tells me that now he has instructions, and he is busy adding more producers, so as to bring up the total power of the station with producer gas for the electric light, to 3,600 horse-power, a very creditable result.

A very great point about the suction producer, in addition to its being a motive power much cheaper than can be got with coal gas, is the possibility of its application in many other ways, and for many other purposes; for example, for ships and motor cars. There is a large field open to the engineer who can successfully apply suction producers on board ship; many such attempts have been made, and I will refer to some a little later. I may say, of course, that Mr. Dowson is the oldest of the producer inventors and producer manufacturers, and I have given his name the preference; but nearly all engineering firms who build engines now, build producers as well, so that we can have suction producers for practically any purpose.

The sizes of the suction producers in operation at present in Britain vary from about 10 horse, as the lowest, up to about 200 horse, as the highest. There are pressure producers also using anthracite which go up even as high as 300 horse, not in one unit, of course, but in several units. Without doubt the suction producer offers very serious rivalry indeed to coal gas, and to compete with it on equal terms, the ordinary coal gas would require to be delivered to the consumer at about 9d. per 1,000

cubic feet. I think that is a matter which gas manufacturers should consider seriously, because a very large part of the present success of coal gas supply depends upon three things: the first is the incandescent gas light; the second is the gas stove; and the third is the gas engine; and the coal gas manufacturers will find that they have a very serious rival indeed in the suction producers. In only one town in England do I know of a case where gas is supplied at anything like the above price. Mr. Carr, the gas engineer of Warrington, sells his gas for power purposes, at 1s. per 1,000 cubic feet—a very admirable thing to do, and an example worthy to be followed by other gas manufacturers if they can.

Interesting developments, it seems to me, are very sure to follow the keen competition which has now set in between these two sources of power, coal gas and suction producer gas.

Many attempts have been made to utilise cheap bituminous fuel for producers, but so far the early commercial stage only has been reached. Commercial success here will come in the near future, owing to the great further reduction in the price of fuel for gas. In the present suction producers, the fuel used is anthracite, and anthracite in London, and wherever there is much carriage, comes to about 24s. a ton. If one could use ordinary engine slack, which can be got at most places at 10s. or 12s. a ton, or even less, one would have a corresponding reduction in the cost of motive power, and instead of coming out at a ninth of a penny, the cost might run down to as low as a twentieth of a penny.* Messrs. Crossley have recently produced a bituminous producer which seems to be working very fairly well. I have only seen one at work but it was working very well indeed. It is rather larger and has more plant about it than an anthracite producer, but still the fuel is so cheap that no doubt it is worth a great effort to get something of that kind. Other attempts have been made, and I wish to distinguish between the two classes of those attempts. There is not much difficulty in making producer gas for gas engines from bituminous fuel, if you are content to put up a large scrubbing plant such as is used with the Mond producers, and such as is used in a gas works; but people using steam boilers are accustomed to see a very large generation of power in a very small boiler space, and they do not look upon the large costly plants which are used in some places, although very useful, as solving this particular problem of getting a producer that will work just like a steam boiler with the ordinary fuel. So much for the suction and producer gas generally.

I must now consider shortly the question of blast furnace gas. Mr. Thwaite—I am glad to say an Englishman—demonstrated in 1895 that the so-called waste gas from blast furnaces could be used in gas engines. He built an engine and plant which was very successfully applied at a blast furnace in Britain, only on a relatively small scale. He showed quite clearly, however, that such gas from blast furnaces could be efficiently used for the purpose of motive power, and that it did not want a too expensive course of scrubbing. In England his work was not taken up with any enthusiasm—one does not quite know why, but some German and Belgian engineers took the problem up with great earnestness. The first to attack the problem of using blast furnace gas, after Mr. Thwaite, on a really large scale, was the Cockerill Company, at Seraing, in Belgium. They fitted up a 200 horse-power gas engine, designed by M. Delamare-Deboutteville, who unfortunately died some time ago—a very able engineer, who devoted himself to large gas engines. They further took gas from the blast furnaces of the works at Seraing, and they found that it would operate a 200 horse-power engine practically without scrubbing at all. The gas engineers in Britain, and, in fact, all those who had had experience in gas engine work, had always felt that the great difficulty in attempting to work blast furnace gas at all was the difficulty of scrubbing, because a very small amount of grit or tar coming in with the gas spoils an engine. The manager of the works, Mr. Greiner, a very able engineer, became so delighted with this success, and with the absence of scrubbing, that he wrote a very interesting paper, in which he announced that the scrubbing difficulty, and the dust difficulty, was a myth of the imagination of engineers; and he built a very large Cockerill engine, which was exhibited in Paris, and which was called a 1,000 horse power engine. He got that to work successfully. Then he took orders for a very large installation in another part of Germany, at Differdingen, and when he got his plant to work there, he found unfortunately that what was true of Seraing was not true of Differdingen. He found that both his pistons and his valves were in serious trouble in a very

* Scotch anthracite can be delivered at Glasgow at 15s. per ton, so that in Scotland power may be obtained at a cost of about 1-15th of a penny per horse-power hour.

short time because of dust. He found then that dust in gas depended very largely on the composition of the iron ore which was being smelted. In one district a gas was obtained which was practically free from dust; in another district the gas was laden with a fine silicious dust. There were two difficulties: one was the dust, and the other was the tar. For a long time very considerable effort was made on the Continent to get over these difficulties, partly by scrubbing with ordinary scrubbers, such as are used in ordinary gas works, and partly by using a centrifugal separator, whirling round the gas with a great velocity, and a spray of water, they were able to separate out both tar and dust, and that difficulty may be said now to have been removed. Another difficulty was the cooling of the gas: as the gas leaves the blast furnace it is very hot, and to cool that great volume of gas, many cubic feet an hour, would be a difficult matter with water, so that air cooling is mostly used.

As the result of this work, there are now on the Continent quite a number of installations of engines using blast furnace gas. At Hoerde there are two distinct systems in operation—the Deutz and the Oechelhauser. The Koerting and Cockerill engines are also largely used.

For a time English manufacturing engineers fought rather shy of these engines, because the risk seemed too great; but now the subject has been thoroughly taken up, and the engines are being established at a very considerable rate in this country. There are three places where they are at work: One is at Messrs. Cochrane's Works at Middlesborough, where they have two Cockerill engines, one 500 horse tandem double acting, which works very well indeed, and another large engine of 600 horse-power, with a single cylinder. Then at Sir Alfred Hickman's, at Wolverhampton, they have several systems at work, including Cockerill, Crossley, and Premier.

Messrs. Mather and Platt, of Manchester, too, have taken up the subject, and they have built engines for blast furnace and producer gas—the Koerting 700 horse for blast furnace gas, particularly.

Messrs. Beardmore, in Glasgow, have now running a large Oechelhauser engine driving a rolling mill, and they have arranged a gas plant using bituminous fuel and scrubbing very extensively in order to make the gas fit for use in the gas engine. Altogether there is a very considerable movement at present, and I have no doubt in the very near future we shall have very many of these large engines working and utilising some part at least of this waste 1,000,000 horse-power of gas.

I do not, however, think that English engineers have been too slow. In England I consider that we have done our full share, both in the theory and practice of the gas engine, although on the Continent, no doubt, they feel the want of the large gas engine more than we do on account of the greater cost of fuel. Now that the attention of English ironmasters has been called to it, they will undoubtedly find the large gas engine help them in the struggle against other nations.

I now come to another important matter, and that is the question of the distribution of gas from a central station. The production of power gas for distribution from a central station has long been a favourite scheme of many engineers. Many years ago the late Sir William Siemens was very much in favour of such a scheme, and he for a long time advocated the establishment of central power gas stations and the distribution of gas for power from central stations—not gas for lighting. A very great and important experimental installation is just on the point of being completed for the South Staffordshire Mond Gas Company. I am informed by the engineer of the station that this great establishment will set to work in about a month, and will distribute cheap fuel gas over an area of something like 120 square miles. The maximum supply with the present plant, although there is room for extension, is something like 15,000 horse-power.

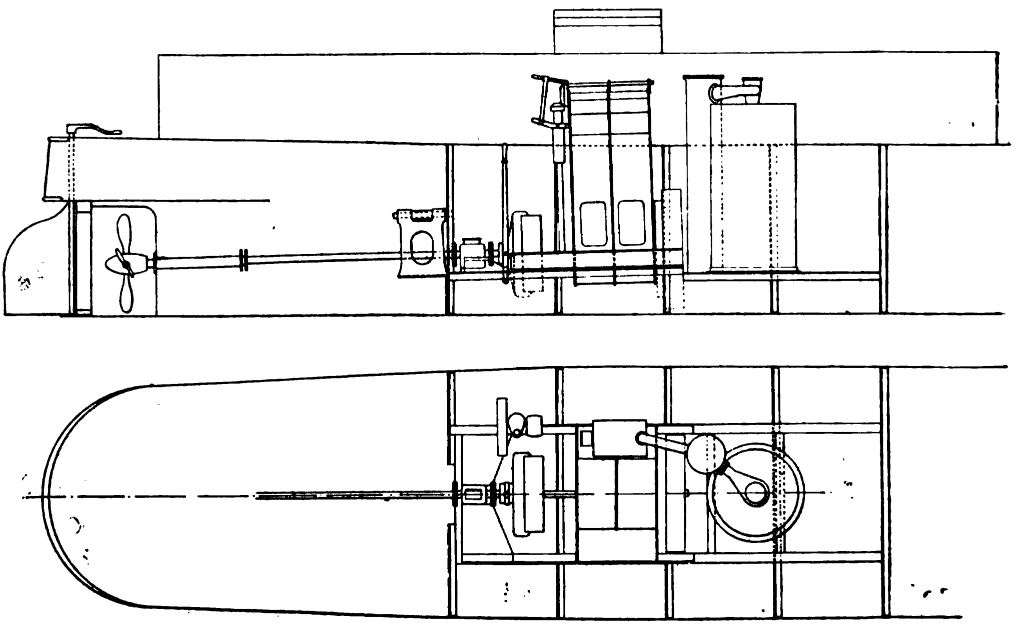
The Mond gas differs from ordinary producer gas in this: in addition to making the gas, the ammonia that is in the coal is saved. Many coals contain a proportion of nitrogen, and if these coals on being decomposed are not heated too highly, ammonia is formed and is not decomposed. To keep the temperature of the producer down sufficiently, the Mond practice is to flush the producer through with a very large volume of steam in addition to the air—much more steam than is wanted for the chemical decomposition. About 2½ tons of steam are used for every ton of fuel. The inflow of steam into the producer has two purposes; the one is that it keeps down the temperature and prevents the ammonia being lost; the other is that it prevents the formation of clinker, and the stopping up of the producer. In this arrangement to get the ammonia out, it is necessary after scrubbing and getting the

tar out of the gas to scrub the gas in great acid towers, making quite a gas works installation. This does not belong to the type with which I consider the producer should be concerned, that is, the type of producer which takes the place of a steam boiler, and does its work with no more complication than the boiler.

To distribute the Mond gas, it is necessary to put it under some pressure, because the volume required is so very great. The calorific value is only about one-fourth or one-fifth that of ordinary coal gas. The consequence is that to distribute this gas over large areas it is necessary to put it under very much heavier pressure than is used with coal gas. The installation is therefore provided with a compressing house, intended to compress the gas for delivery in the mains. Mr. Humphrey tells me that a test was made recently at this establishment in which air was delivered along a main five miles long from these compressors at the rate of one and a-half cubic feet per hour. If that were pumping gas, this rate would be fully equal to about 15,000 horse per hour. This rate of delivery was attained with a pressure of 10 lbs. per square inch at the central station, so that it is thought that ample pumping plant and ample pipe accommodation have been provided to take the enormous volumes of gas necessary in this system. It will be very interesting indeed when this installation starts. It is one of the largest and most important experiments in progress in the world, and all engineers look with interest upon it, and wish it every possible success.

In carrying on the operations of this great station, it is required to pump water and acid to absorb the ammonia and to keep up the general circulation in the system. A large pumping house is, therefore, provided in addition to the other large erections, the whole forming a very important station.

FIG. 32.



CANAL BARGE *Duchess*, FITTED WITH PRODUCERS. BUILT BY MESSRS. THORNYCROFT.
Length, 71 feet. Beam, 7 feet. Draft, 3 feet 9 inches. Speed, 6 miles per hour. B.H.P., 30.

The same trouble which is met with in blast furnace gas is also met with in gas of the type of Mond gas, the tar being the great difficulty. If there were no tar to deal with, all these matters would be very simple, but in a large installation, such as this South Staffordshire Company's installation, there is no real difficulty, because there is space enough to build up the scrubbers; but if anything of that sort had to be done on board ship, say, it would be a very different matter.

Another development which is taking place —and it may be said to belong really to the future—is the application of internal combustion motors to boats or ships of different

kinds. The first application—and, of course, the easiest one—has been the application of petrol engines for the purpose of motor boats. An example of this application is found in the Napier motor launch—a very interesting machine. This launch has a single shaft propeller—a four-cylinder engine with all the same kind of gear and parts for operating and reversing that is used in the motor car. In fact, so far as these motor boats are concerned, they may be practically considered to be boats in which motor-car engines have been fitted with all the usual gear—that is, the usual clutch and reversing gear. There is no attempt to reverse directly by the engine.

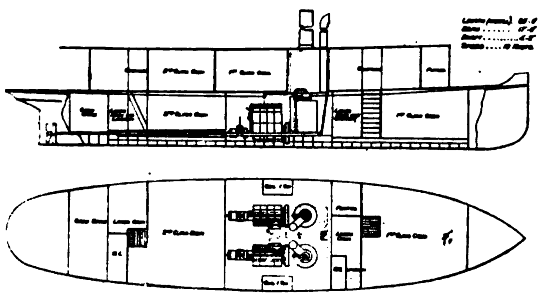
I now come to the second and much more important application, viz., the application of producer gas, the suction producer, or any other producer, to sea-going purposes. The sources of petrol are so limited that one cannot expect to do anything great in the way of motive power at sea with petrol. There is not enough petrol, and there is not enough oil, in the world. Any sort of run upon petrol by a huge use of petrol engines would at once put up the price, because the amount of petrol in the world is so small. In fact the amount of the oil is so small, that if it were attempted to run anything like the tonnage of this country with petrol or with oil, it would be impossible to get enough petrol and oil in the world to do that. The consequence is that the real marine problem can only be solved when coal in some form is used on board ship. M. Capitaine, of Frankfort, has built a producer gas tug at Frankfort-on-the-Maine, and Messrs. Thornycroft, in this country, have taken up the Capitaine designs. Fig. 32 shows the first boat built in England, a canal barge, *The Duchess*, which is to have a motor of 30 horse-power on board. This boat is now being built, and is expected to be going very shortly; great economy is expected, 30 horse-power being obtained at a cost of about 3d. an hour, *i.e.*, one-tenth of a penny per horse-power per hour for fuel, comparing most favourably with steam.

Fig. 33 shows a passenger boat which Messrs. Thornycroft are now building with suction producers. In this case, double cylinder engines and two producers are used. It is noticeable into what a small compass the cooling and scrubbing plant are arranged. By using good anthracite and a very fine water spray, M. Capitaine succeeded in reducing the compass of his scrubbing plant to very small limits indeed.

These experiments are extremely important, and I have no doubt at all that in a few years huge liners will be run without steam at all, with nothing but gas plant and gas engines on board, using electricity for their auxiliary power.

Now with reference to the line of advance in future. There are many things still open for ambitious young engineers to do in this line of work, both in the improvement of the engines themselves, in the production and supply of fuel, and in the application of these engines to many other purposes. First, then, with reference to the thermal efficiency—the thermal efficiency of these engines has improved enormously. In 1882 the indicated efficiency, that is, the amount of heat converted into work

FIG. 33.

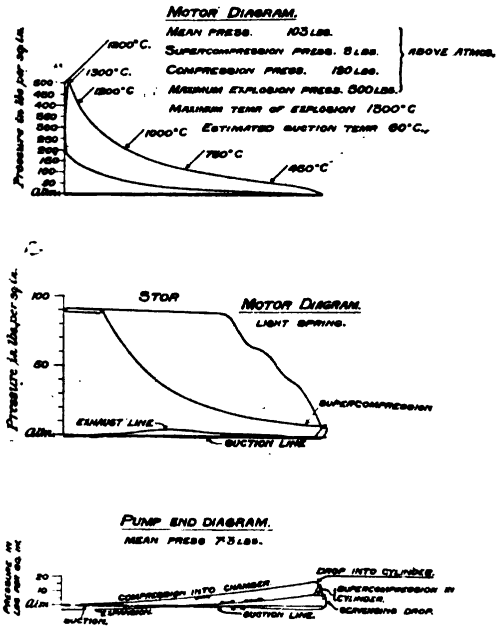


PASSENGER BOAT, BUILT AND FINISHED WITH SUCTION PRODUCERS BY MESSRS. THORNYCROFT.

in an ordinary first-class gas engine, was 16 per cent.; in 1900 it had risen to 31 per cent.; and, at present, that is, since 1900, in the last four years, the efficiency of a large first-class gas engine may be taken at as high as 35 per cent.; that is, in some cases more than one-third of all the heat given to the engine is converted into indicated work. That change has taken place since 1882, and it is natural that one should ask one's self, "Can these engines be much further improved?" I have no doubt they can. A little consideration of the different cycles will show that if the constant pressure cycle could be adopted, and the difficulties of the constant pressure engines overcome, we should be able to get an engine the same weight as the present constant volume engine, giving instead of a theoretical efficiency of about 48, a theoretical efficiency of about 63 or 64; and we should get a practical indicated efficiency of considerably over 40 per cent. That is one way of increasing the efficiency. There are other ways. One is

to reduce the temperature of the flame. That can be done without losing economy, because, as I pointed out in my first lecture, the efficiency, that is, the economy of any Otto four-cycle engine, is independent of the maximum temperature of the flame, if the temperature of the flame is above the temperature of compression. The consequence is that if we can keep up the average pressures, we may reduce the temperatures if we like.

FIG. 34.



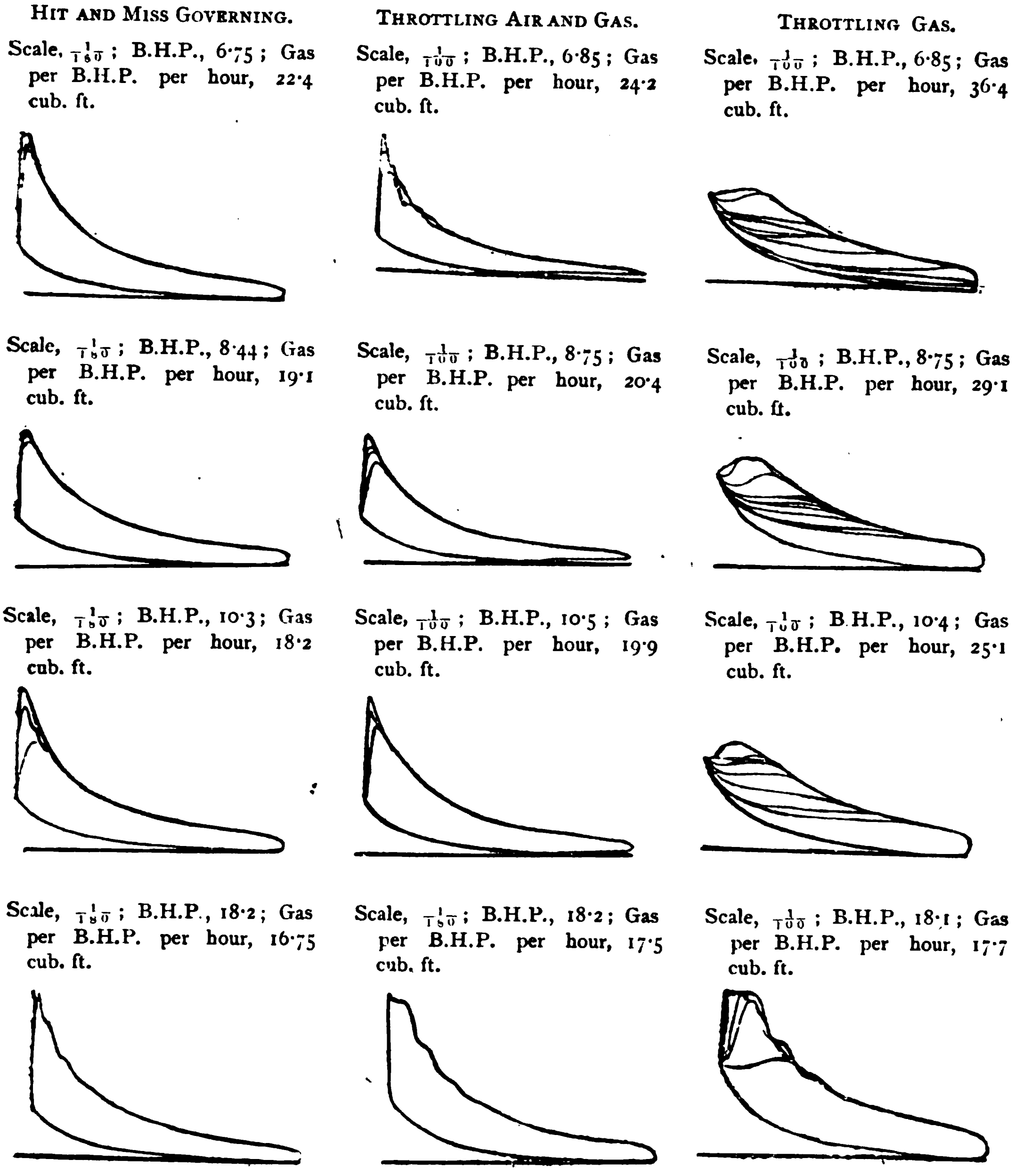
DIAGRAMS FROM NATIONAL AIR SUPERCOMPRESSION ENGINE.

With regard to the large engines, particularly, it is desirable to reduce flame temperatures to the lowest possible point at which complete combustion can be attained, at the same time increasing the charge weight in order to maintain mean pressure. In this way the cylinder and pistons are enabled to withstand the strains of unequal expansion, and troubles from irregular ignition of various kinds are avoided. I have been working on these lines with fair success. Fig. 21 shows a 300 horse-power engine at work in St. Helens on the air supercompression principle, designed by myself in conjunction with my colleagues at the National Gas Engine Company. In this engine a considerable quantity of air under pressure is introduced into the cylinder at the end of the charging stroke, the air having been compressed in front of the piston; this raises the pressure before the usual compression commences to about 7 lbs. above atmosphere. The compression stroke then proceeds, and explosion and expansion take place in the usual manner. Fig. 34 shows diagrams taken from this engine, and it will be seen from these diagrams that the temperature of combustion is reduced to about 1,200 C. as compared with the 1,600 C. or 1,700 C. usually reached, while the pressure is kept up, the mean pressure being as high as 103 lbs. per square inch. This engine works very well indeed; but it involves some little extra expense in the air-pump arrangements. In order to reduce the cost, I have designed a method of exhaust supercompression. In this method the exhaust gases from the engine are trapped under pressure and cooled, and then introduced at the end of the charging stroke instead of air, as above described. This method is now working on an engine of 10 inches by 18 inches, and we intend to build a large engine utilising the principle. The object aimed at in both these engines is to diminish the temperatures, and so diminish heat loss and avoid pre-ignitions.

Many attempts have been made to compound gas engines, but none have, as yet, succeeded. The more important points for immediate attention in connection with the development of the gas engine, or internal combustion motor, are not on the thermo-dynamic side; the more important points are on the mechanical side—that is, to improve the number of impulses, to improve the mean torque so that it may be more regular, and to produce methods of governing that are quite regular and quite reliable. Fig. 35 shows the results of a set of experiments made by my colleague, Mr. Bradley, of the National Gas Engine Company, on a 9-inch by 17-inch engine, illustrating the three different modes of governing in use all over the world at present in these engines. The diagrams in the first column show the effect of the ordinary hit-and-miss type, which is so much used in Britain and is the most economical of all. The second column shows the effect of throttling air and gas, and the third column the effect of throttling gas alone. A series of diagrams of brake tests were made at different loads. With the hit-and-miss governor, at a brake horse-power of 18·2, the gas consumption is 16·75 cubic feet per B.H.P. At a brake horse-power of 10·3, the consumption has gone up to 18·2; at brake horse-power 8·44 the consumption is 19·1. With a third of

the power the consumption has gone up to 22·4 cubic feet per brake horse-power. That is a very good result, even at the light load. The second column of diagrams show the proportion kept unaltered. Here we find that at 18·2 B.H.P., the consumption has gone up a little to 17·5 cubic feet per brake horse-power; at 10·5 B.H.P. it has gone up to

FIG. 35.



COMPARATIVE DIAGRAMS SHOWING RESULTS PRODUCED BY VARIOUS METHODS OF GOVERNING.
National Gas Engine; Type "R"; 9″ Diameter; 17″ Stroke; 200 Revs.

the same engine governing on the throttle, as is the practice on petrol engines, that is, the gas and air are choked by the governor together, so that gas and air shall be equally choked, and the total supply diminished; but 19·9; with 8·75 B.H.P. it is 20·4; and with 6·85 B.H.P. it is 24·2. There you find a very fair governing indeed at a third of the load. On the third system, not throttling the mixture, but throttling the gas only, so that the

proportions of gas and air are changed, we get at a brake horse-power of 18·1 a consumption of 17·7, which is about the same as on the second system, where the mixture is throttled. Then with brake horse-power 10·4 we have 25·1; with brake horse-power 8·75 we get 29·1; and with 6·85 brake horse-power, we get a consumption of 36·4 cubic feet per B.H.P. hour, so that this method of governing involves an enormous disadvantage. This is, however, one of the methods that is sometimes used in large engines. The best known method of governing for giving uniformity of impulse and fair economy at the same time, is undoubtedly throttling the mixture, and that is the method which is used in most large gas engines. These matters are open for the future. In marine work, too, it is necessary to be able to reverse the engine itself. In all the marine gas engines or marine petrol engines which have been used yet, the engine is not reversed; the clutch is thrown out, and the gear is altered. That does very well for a moderate power engine, but it would not do for a big 5,000 horse-power engine. The problem of reversing the engine and dispensing with the reversing clutch gear is one that still awaits solution.

I will only say one word about the gas turbine, and that is this: until someone invents or discovers an efficient gas and air compressor of the turbine type, there is no possible hope for efficiency with the gas turbine. The problem is very much more difficult than the problem of internal combustion in the cylinder. It must not be assumed that the same things which hold good in the steam turbine hold good in the gas turbine.

In the direction of improved fuel, lighter producers have to be invented and will be invented. They have to be made easily capable of using any fuel, bituminous and non-bituminous, and that will all come. Special engines have been designed for motor cars and heavy goods carriages with gas producers, and I have no doubt that a suction gas producer, with, say, wood charcoal fuel, could be made for a motor car. It would not be quite so light as the present motors, but very nearly so, and it would be very much more economical and safe. At first, however, the combination of suction producer and gas engine will be applied on very heavy vehicles and canal boats.

In concluding, I would like to read to you two paragraphs from a paper read by me before the Institution of Civil Engineers exactly twenty-three years ago—in 1882:—

"The gas engine is as yet in its infancy, and many long years of work are necessary before it can rank with the steam engine in capacity for all manner of uses; but it can and will be made as manageable as the steam engine in by no means a remote future. The time will come when factories, railways, and ships will be driven by gas engines as efficient as any steam engine, and much more safe and economical of fuel. Gas generators will replace steam boilers, and power will not be stored up in enormous reservoirs, but generated from coal direct as required by the engine."

Well, I was in those days much younger and more enthusiastic, and perhaps more venturesome, and more liable to prophecy things; but I think I may claim that that prophecy, made twenty-three years ago, if not absolutely true, is rapidly becoming true. All that I would like to say now is, that twenty-three years ago the gas engine was in its infancy, but now it is in its early manhood, with a very long career of usefulness before it.

MEXICO.

The economic progress of Mexico during the last quarter of a century has been very remarkable, and the Government of Mexico has acted wisely in directing special attention to this development. The statistics that prove it are to be found in Blue-books, but Blue-books have not a large circulation, whereas a small pamphlet will be read by many. Such a pamphlet, called "Mexico: Yesterday and To-day, 1876-1904," has just been published under the auspices of the Mexican Government, and is referred to by Mr. Consul Jerome in his report on the trade and commerce of Mexico just issued (No. 3429, Annual Series). It may be interesting and useful to note some of its figures.

Take first telegraphic communication. The following tables indicate the growth:—

		1876.	1903.
Federal Government telegraph lines ..	(miles)	4,434	31,270
State do.	,,	814	3,239
Private do.	,,	749	1,934
Federal Government telephone lines ..	,,	—	208
State do.	,,	—	10,030
Private do.	,,	6	13,125
Receipts from the telegraph service.	(dols.)	93,302	2,119,281
Offices, including two with wireless telegraphy installations..........		109	418

One of the principal causes of the progress, commercial and social, of Mexico has been the development of the railways. In Northern Mexico construction was comparatively easy, but in the central table-

lands high mountain ranges had to be traversed, while in the south and on the coast the climate rendered construction work very arduous. Nevertheless, development has been very remarkable, as the following figures show :—

	1876.		1903.
Railroads in operation	6	..	87
Miles constructed	567	..	16,285†
Passengers carried....	4,281,327	..	50,343,744
Merchandise (tons) ..	133,000	..	6,668,499
Electric tramways (miles)	—	..	265
Animal traction tramways (miles)	470	..	2,855
Passengers carried on tramways..........	*	..	38,452,675
Transported on tramways (tons)........	*	..	25,973
Federal subsidies to railways (dols.)	5,151,905	..	144,891,743

The revenue of the Federal Government in 1876 amounted to $19,088,158, in 1903 it was $81,061,078.

The increase in the shipping carrying on the international trade of Mexico, as shown in the following table, is of exceptional interest, the minor carriers being left out :—

Flag.	1885-86. Steam. Number of Vessels.	Steam. Tons.	Sailing. Number of Vessels.	Sailing. Tons.
British	132	155,930	31	10,110
United States	522	716,799	174	37 511
Norwegian	3	1,149	82	27,058
Spanish...	79	125,189	67	6,509
German...	36	46,736	87	29,982
French	14	22,631	20	6,317
	1902-03.			
British	305	808,303	138	31,971
United States	238	694,572	210	6,412
Norwegian	201	293,928	55	25,201
Spanish...	64	248,231	5	977
German	85	272,008	23	32,942
French	14	80,234	...	...

It will be noticed that whilst the Americans carried less in 1902-3 than in 1885-6, British steam tonnage increased more than five-fold, and whereas in 1885-6 it was little more than a fifth of the American, in 1902-3 it exceeded it. The comparative increase in German tonnage has been even greater than in British.

One of the most interesting features of modern Mexico is the development of education. In various parts of the republic, even in the most unexpected places schools similar to the Board schools of England exist. The statistics given by the writer of the pamphlet referred to above, Mr. Madden, are noteworthy.

* No data. † 16,387 miles in 1904.

GOVERNMENT SCHOOLS (FEDERAL, STATE, AND MUNICIPAL).

	Number. 1876.		1903.
Primary schools....	4,542	..	9,546
Pupils— Males	101,748	..	383,381
Females	48,981	..	248,134
Secondary and high schools	173	..	351
Pupils— Males	10,654	..	25,051
Females	3,316	..	16,446
Total school teachers and professors— Males..........	3,200	..	8,063
Females........	1,228	..	6,393
	Dollars.		Dollars.
Expenditure	2,049,045	..	9,060,325

The private schools (Catholic, Protestant, and Secular) also show considerable increase. 764,353 children of both sexes attend the 11,590 schools at present existing in the republic. It is interesting to note the number of women who in the last five years have entered into competition with men as clerks, typists, shorthand writers, in the post and telegraph offices, and as shop assistants. There are to-day 124 public libraries, 39 scientific associations, and 37 museums of all kinds in Mexico, and while electricity was unknown in Mexico in 1876 now there are some 100 towns lighted by electricity and 250 plants for power and industrial purposes in various parts of the Republic.

Turning to British trade with Mexico, and having regard to the great development of the country and consequent increase in its requirements, it cannot be said that the following figures are very satisfactory :—

	Value. 1874-75 (Fiscal Year).		1903-04 (Fiscal Year).
Imports into Mexico from United Kingdom	£1,731,433	..	£2,003,230
Exports from Mexico to United Kingdom	£1,843,967	..	£2,499,146

Going more into detail the following figures show the value of imports into Mexico from principal countries during the years 1899-1904 :—

Years.	United States.	United Kingdom.	Germany.	France.
	£	£	£	£
1898-1900.......	6,205,283	2,096,640	1,334,769	1,351,428
1900-01	7,037,991	1,984,910	1,415,990	1,312,847
1901-02	7,806,438	1,652,826	1,290,441	1,257,172
1902-03	8,102,909	2,123,069	1,914,802	1,307,885
1903-04	8,521,754	2,003,230	1,908,216	1,494,415
July 1 to Dec. 31, 1904	4,555,533	998,596	1,054,365	814,728

It will be seen that in the last half of 1904 Germany takes the second place, while the United Kingdom drops to the third, and the preliminary statistics for the first months of the present year show that the Germans maintain their place. The increase in imports from Germany are due, in great measure, to increased facilities owing to the improved direct steamship service between the two countries, the agents from the German lines doing all they possibly can to obtain freight. Mr. Consul Jerome is inclined to attribute the falling off in British imports to the lull in 1904-5 in railway construction, and consequent diminution in the imports of railway material, added to the successful competition in this trade by the American Steel Trust, and the fact that the rails are now also being manufactured in Monterrey.

Mr. Consul Jerome refers with reluctance to British trade methods, which, in his opinion, militate against the increase of British trade with Mexico, and give commercial rivals avoidable advantage. He refers more particularly to the formalities required in the shipment of goods and to Mexican customs that ought to be observed. Probably in no country in the world is competition keener than in Mexico, and where mistakes are made and continually repeated in spite of protests of both the consignees and resident representatives of British firms, advantage is immediately taken by competitors. Many of these mistakes are apparently made, says Mr. Jerome, "by permitting the export business of a house to be conducted by a junior clerk, and the partners not giving matters of detail the amount of consideration which would prevent any repetition when once mistakes have been brought to notice." Mexican Customs regulations require that besides the previous Consular invoice, a signed copy or stamped bills of lading covering goods imported into the Republic of Mexico must be presented at the Custom houses. As this copy is retained by the Custom authorities it follows that the consignee must also have a stamped and signed copy too for him to obtain the delivery of the goods from the carriers. "British firms are particularly refractory as to these regulations. The result has been a good deal of annoyance, and a considerable drop in the volume and value of British imports. I know," continued Mr. Jerome, "of one firm who have instructions to the above effect printed, which they send with every order to their correspondents in the United Kingdom, and yet in nine cases out of ten the request is not complied with." Mr. Consul Jerome proceeds to give many useful hints to shippers who may be recommended to study the whole of his present very valuable report. Among other things he warns the British public against the allurements of promoters who may have rubber "propositions" to dispose of. He says that the numerous plantations for the cultivation of rubber have hitherto not proved successful undertakings; that is, as dividend earners; and much harm has been done to the genuine ventures of this kind by the operations of a number of fraudulent concerns having their head quarters in the United States. Foiled in their own country, the promoters of these schemes are now turning their attention to both the United Kingdom and Canada. It may be noted that bananas, cultivated in Mexico hitherto only for home consumption, are now beginning to be grown for export. Having regard to the shortness of the haul to points in the United States the Mexican grower should have it all his own way, and the Mexican banana, and other tropical produce, is likely soon to compete very seriously with those from Jamaica and other West Indian Islands.

THE COSTA RICAN BANANA INDUSTRY.

The banana industry, unknown to Costa Rica twenty-five years ago, has reached such proportions, especially within the last few years, that bananas now form the main export of the country. It is no longer an industry in its infancy, but an industry as important as that of coffee, which for a long time has been the mainstay of the Republic. At the close of 1904, about 50,000 acres were devoted to banana growing in Costa Rica, of which 90 per cent. are owned by the United Fruit Company, a corporation organised under the laws of New Jersey, and controlling probably 75 per cent. of the total production. At present the market for this fruit is highly encouraging, and bids fair to continue so for many years to come. The United States representative at Port Limon says that the trade was exclusively confined to the United States until 1902, when it was introduced in England, with gratifying results to the exporters. France, Germany, Italy, Spain, and other European countries, do not as yet consume the banana, but as soon as a substantial increase in the acreage is reached, and with the present facilities for transportation and the use of ships equipped with cold storage, the market should, and no doubt will, be extended to those countries, with results equally gratifying as in England. There appears to be very little fear of the demand for bananas ever ceasing to exist. Bananas are not luxuries alone, but nutritious food, and being cheap, will always be used by all classes and for many purposes. The amount exported from Port Limon during the five fiscal years ended with June 30, 1904, was as follows, in bunches:—1900, 2,804,103; 1901, 3,192,104; 1902, 4,427,024; 1903, 5,261,600; and 1904, 5,760,000. During the six months ended December 31, 1904, the exports amounted to 2,911,071 bunches. As shown, banana exports have more than doubled during the last five years, and present indications are that the exports will double again during the next five years. As an investment, the United States representative says: "Taking into consideration the quick returns and the readiness and ever-increasing sphere of market, I consider banana cultivation quite profitable. On a conservative estimate 40 per cent.

per annum can be realised to investors, under good management and normal conditions." The following figures show the probable cost and profit on a tract of 100 acres planted in bananas. Original outlay—land (£4 per acre), £400; reducing land and bringing it to a banana-bearing condition (£10 per acre), £1,000; total, £1,400. Gross returns, 180 stems per acre per annum, £1,116. Expenses—cutting and hauling the fruit, and keeping the plantation clean, £288, manager (£20 per month), £240; total, £528. Net return on investment, £588. The entire banana crop at present is sold to the United Fruit Company, which works a railway system through the fruit districts, and pays about sixteen pence per stem on delivery alongside their track. Under very favourable circumstances, a banana plant may give a stem of fruit in nine months, but it generally takes from fifteen to eighteen months for the average plantation to be in full bearing. The life of a plantation varies according to the fertility of its soil and topographical situation. Some soils may need a rest in six or seven years, while others may last practically for ever, as in cases where periodically enriched by alluvial deposits. Plantations fifteen years old yield at the present time as many bananas as they did in their second or third year. Sandy loam, through which water or rain will freely percolate, is the best soil for bananas. The stalk needs a large amount of rainfall for its successful development, but water must not be allowed to remain on the surface or immediately under the surface of the soil surrounding it, lest the water be heated by the tropical sun and become stagnant, in which case it may kill the plant. Jamaican negroes are exclusively employed as labourers, and their average pay is about 3s. a day. The negro is immune from yellow fever, is indispensable, and the only person really adapted to the work required in districts where, by reason of the richness and more or less swampy nature of the land, mosquitoes abound, and the dangers of contracting disease are comparatively great. The implements used in cultivating bananas are steel machetes, axes, shovels, and ploughs. Many plantations are equipped with narrow-gauge railways and horse cars for hauling fruit. The rails used are very small. Machetes, axes, and ploughs are generally imported from the United States. Shovels come from the United Kingdom. Rails are imported from the United States and Germany, but chiefly from the latter country on account of the difference in prices. It is understood that fine flour can be made from bananas, and that fibres from the leaves and stalks could be extracted and successfully worked, but as yet nothing in this direction has been done in Costa Rica.

SALT MINING.

An interesting paper on Salt Mining and Salt Manufacture in Cheshire, has lately been read by Mr. John Hall, before the Manchester University Union, from which the following particulars are taken:—

The town of Northwich is one of the Cheshire Wiches or Salt towns. It is situated almost in the middle of the county of Cheshire, on the River Weaver, which is capable of allowing vessels of two hundred tons burden and upwards to navigate its waters. This river empties into the River Mersey, near the small town of Frodsham. Runcorn and Liverpool, near to this place, are the shipping ports. Salt, or chloride of sodium, was made from a natural spring at Northwich in the earliest times certainly by the Romans and Saxons. A small salt pan made of lead, three feet long by two feet wide and four inches deep, was dug from the earth a few years ago; it is supposed to be Roman, and is now in the Museum at Northwich. In the Domesday Book, Northwich is mentioned as Wich. It was at Northwich that rock salt was first discovered in England, in the year 1670.

Prior to this date, the manufacture of white salt, chloride of sodium, Na.Cl., from brine, had been very small.

In the year 1679, the quantity made at Northwich was estimated to be about 15,000 tons in the year. During the present century, the quantity of salt manufactured has increased very much, and now half a million tons of white salt and over 60,000 tons of rock salt are sent away every year from the Northwich district. The beds of rock salt underlying the town and neighbourhood of Northwich have been proved to extend over an area of four square miles. It is probable that they are even more extensive. These beds occupy the lowest portion of an old salt lake of Triassic times, which covered a very much larger area than that of the existing beds of salt, as is shown by the Keuper marls which were deposited in it. There are two main beds of salt, or one bed divided by marl. The salt is overlain by the saliferous Keuper marls, and these by the boulder clays, sands and gravels. The first bed of salt is met with at a depth of about 40 yards, varying according as the surface varies. Its thickness averages about 25 yards. Below this bed there is a stratum of much-indurated Keuper marl, about ten yards in thickness, and this is succeeded by the second or "bottom" rock salt. This second bed of rock salt is about 35 yards thick. It is in this lower bed of rock salt, which was not discovered until 1781, that all the existing rock salt mines are worked. The earliest mines were worked in the first bed of rock salt, afterwards, when the second bed was discovered, the first bed was abandoned.

The brine from which the white salt is manufactured exists naturally only on the surface of the first bed of rock salt. The water from the rainfall, making its way to the rock salt, dissolves the salt and becomes brine. Salt is very soluble, and water, when fully saturated with it, contains nearly 27 per cent. Some of the mines in the second stratum having been worked out, have filled with brine, and

are large reservoirs out of which a large portion of the brine for the mauufacture of white salt in the Northwich district is pumped. There are two distinct methods of obtaining the salt from the salt beds. The first is by ordinary mining, when the natural or rock salt is obtained. The second is by pumping the brine, and then obtaining the salt by evaporation of the water in iron pans.

In preparing common salt, the brine is first raised to a boiling heat, with a double view of bringing it as quickly as possible to the point of saturation and of clearing it from its earthy contents. The fires are then slackened, and the evaporation is carried on for twenty-four hours with the brine heated to 160° or 170° Fahrenheit. The salt thus formed is in quadrangular pyramids, or hoppers, which are close and hard in their texture. The remainder of the process is similar to that of making stoved salt.

Large grained or fishery salt is made with an evaporation conducted at the heat of 100° or 110° Fahrenheit. No perceptible agitation, therefore, is produced in the brine, and the slowness of the process, which lasts from seven or eight to ten days, allows the chloride of sodium to form in large and nearly cubical crystals, seldom, however, quite perfect in their shape. For ordinary domestic uses stoved salt is perfectly sufficient. Common salt is adapted to the striking and salting of provisions which are not intended for sea voyages or warm climates. For the latter purpose the large grained or fishery salt is peculiarly fitted.

For this latter purpose, and for the salting of fish a few years ago, large quantities of bay salt were imported to this country from abroad, and was much esteemed until an exhaustive chemical analysis proved that it was inferior to the English-made large-grained fishery salt. After this the English make was more in favour for salting fish, &c., and now enjoys a very large consumption.

AUSTRALIAN INDUSTRIAL THRIFT.*

A leading financial authority lately declared that the savings bank constitutes the true criterion of the well-being of an industrial community. Judged by this standard, the condition of the industrial classes in the Commonwealth is superior to that of their brethren in Great Britain, the average amount of savings bank deposits in Australia being £31 17s. 2d. per head, against £18 4s. 10d. in the Mother Country. And this is exclusive of industrial investments in land and building associations and other financial institutions. In one respect the Australian savings banks differ from most of those in Great Britain, being more or less under State control, and thus efficiently safeguarded. They are of two classes, those worked by the State in conjunction with the Federal Post Office, and those managed by commissioners or trustees, who are generally nominated by the State Government. In New South Wales the Trustee Savings Bank was established in 1832, and the Government Savings Bank in 1871. In both institutions sums of one shilling and upwards may be deposited, but interest is not given on any individual amount in excess of £300 save in the case of friendly societies and charitable institutions. In Victoria, the Commissioners' Savings Bank and the Government Savings Bank have been amalgamated, the new institution being empowered to make advances to farmers and others, in addition to the customary modes of investment. In Queensland, a Government Savings Bank not working in conjunction with the Federal Post Office, and dating from 1865, is in operation. In December, 1895, authority was obtained for the issue of Savings Bank Stock 3 per cent., to enable depositors of upwards of £200, the limit of interest-bearing deposits, to obtain interest on any excess, as it was found that large sums were entrusted to the State Government which could not earn interest under the old constitution of the bank. In South Australia, the existing Savings Bank, established in 1848, like the bank of New South Wales, is administered by trustees, the maximum amount of interest-bearing deposits being £250. In Western Australia, the Government Savings Bank, dating from 1864, accepts interest-bearing deposits up to £300, but the total amount must not exceed £600, nor may more than £150 be deposited in any one year. In Tasmania, there are both Government and Trustee Savings Banks, interest not being allowed on sums over £150. In 1903-4, the number of Savings Bank depositors in Australia was as follows:—New South Wales, 331,956; Victoria, 432,867; Queensland, 80,059; South Australia, 123,455; Western Australia, 56,628; and Tasmania, 47,904; making a total of 1,072,869, or nearly one-third of the white population, according to the census of 1901, showing the Australian industrial classes to be one of the most thrifty peoples in the world. The amount of deposits in each State during 1903-4 was:—New South Wales, £12,344 623; Victoria, £10,582,808; Queensland, £3,741,967; South Australia, £4,202,637; Western Australia, £2,058,619; Tasmania, £1,249,401; making an average total of £31 17s. 2d. per depositor, an amount exceeded only in America, Canada, and Austria-Hungary. The average amount per depositor is largest in Queensland, being £46 14s. 9d., and lowest in Victoria. The element of thrift is most largely developed in the country, where they assist largely in enabling settlers to provide against unforeseen contingencies. The system of book-keeping generally adopted is so efficient that any defalcation has become almost impossible, a fact which explains the confidence of the Australian people in these institutions. Previous to the establishment of the Commonwealth, most of the Government Savings Banks were largely under the control of the postal authorities, but with the transfer

* Communicated by Mr. John Plummer, of Sydney.

of the State Post Office systems to the Federal Government they have reverted to State control, with certain facilities afforded by the Federal Post Office.

GERMAN AND FRENCH ENTERPRISE IN CHINA.

As many German merchants are found to-day in the great cities of the interior of China as in the treaty ports on the sea coast. In Shanghai there are 68 German merchant houses which are doing 22 per cent. of the import trade of the city. In Tientsin there are 29 German houses, which control 45 per cent. of the exports and 60 per cent. of the imports. Fifty per cent of the imports and 75 per cent. of the exports of Canton, China's greatest city, pass through the hands of German merchants. The efforts of German merchants have not been confined to the land alone. The number of ships flying the German flag seen on the Chinese seas and in the harbours of the treaty ports is ever increasing, and this is especially the case on the inland streams. German companies, backed by German capital, are exploiting the coal-fields of Shantung. It is claimed by experts that the coal of Shantung is superior in heating and lasting power to the Japanese coal, and that its use is accompanied by less smoke. This coal is destined to play an important part in the Chinese markets. German capitalists are establishing banks, building docks, factories, mills, and exploiting mines at the present time in nearly every part of China. According to the French Press, the best way to checkmate the increasing influence attending German commercial enterprise in China, in the interest of France, is to construct a railway from Tongking to Yunnan, and thence throuch the heart of China. The commercial activity of German merchants in China, it is added, "should serve as an example and an incentive to French merchants to secure a greater share of the Chinese trade.

OBITUARY.

LORD LINGEN, K.C.B., D.C.L.—Lord Lingen, a member of the Society of Arts of fifty-three years standing, died on the 22nd inst., at his residence in South Kensington. Ralph Robert Wheeler Lingen was born on February 19th, 1819, at Birmingham. He was educated at Bridgnorth Grammar School, and when he went up to Oxford, as a scholar of Trinity College, he possessed a high reputation for his classical attainments. In 1838 he won the Ireland Scholarship, and in 1839 the Hertford Scholarship, in 1840 he obtained a first-class in Classics, and in 1841 was elected to a Fellowship at Balliol. He entered as a student at Lincoln's Inn, and in 1847 was called to the Bar. In 1849 he was appointed to succeed Sir James Kay-Shuttleworth, as Secretary of the Education Department. Twenty years later he became Permanent Secretary of the Treasury, an office which he held with great distinction for sixteen years. On the occasion of the defeat of Mr. Gladstone's Government in 1885, he retired, after nearly forty years service, and was raised to the peerage. In the following year he was made an honorary Fellow of Trinity College, which he entered as a scholar nearly fifty years before. He was created a C.B. in 1869, and K.C.B. in 1878. After his retirement, Lord Lingen did not take any conspicuous part in public life. He was elected an Alderman of the first London County Council in 1889, but resigned his seat in 1892. He was a member of official Committees for publishing a revised edition of the Statutes and the State Trials, and also a Governor of Rugby and Bedford Schools. On April 10th, 1889, he took the chair at a meeting of the Society, when the late Sir Douglas Galton read a paper on the "Sanitary Functions of County Councils."

GENERAL NOTES.

MILAN EXHIBITION, 1906.—An International Exhibition will be held next year to celebrate the completion of the Simplon Tunnel. Attention is drawn in *The Times* to the fact that the time for sending in applications as exhibitors expires (except for live stock, plants, &c., in the agricultural section) on the 31st inst. Application forms and full printed particulars can be obtained in London from the Italian Chamber of Commerce, or through the London Chamber of Commerce. The British Chamber of Commerce for Italy in Genoa is offering every assistance to intending British exhibitors, and is urging the importance of the occasion which the Exhibition offers of comparing genuine first-class British goods with their many misleading imitations. France, Germany, Switzerland, and Austria-Hungary are taking official interest in the Exhibition, and the French Parliament has been asked for a grant of £18,000 for expenses.

NEW CALEDONIA.—Mr. Consul Brophy's report (No. 3431, Annual Series) on the trade of New Caledonia for the years 1903-4 does not suggest a very prosperous or improving state of affairs in the settlement. The island is 250 miles long by an average of 30 miles broad, but the total white population is only 23,000, of whom 12,500 are of free, and 10,500 of convict origin. The town of Noumea contains about 7,000 inhabitants, and of these 2,000 are of penal origin. Agriculture is almost non-existent. Cattle do well, especially towards the

north part of the island, where the pasture is better, but for lack of a good market the cattle breeders are overstocked. Sheep imported degenerate. Nickel, chrome, and cobalt ores are found in large quantities, but owing to the competition of Canadian, Turkish, and other deposits, the prices obtainable leave little profit to the mine owner. The nickel ores of the island are very rich, exceptionally in isolated patches, containing as much as 15 per cent. of metal. In the great Canadian deposits it is only 3 to 4 per cent., but there it is found as a kind of bye product in conjunction with copper, which is not the case in New Caledonia. Of the three large companies working nickel mines in the beginning of 1904, one has suspended operations for the present, having worked out its principal mine at Neponi, and another has closed down its mine at Vohu for want of capital. Something is hoped from the development of coal deposits, and there is a party in the island agitating for a resumption of criminal transportation, but Mr. Consul Brophy sees little likelihood of much early improvement in the economic condition of the settlement.

Foreign Markets.—If Mr. Vice-Consul Dundas is right a good deal more business might be done by British traders with Roumania if they went the right way to work. In his report for 1904 just issued (No. 3432, Annual Series), the Vice-Consul complains that "British firms will not do business except in their own way, and unless they can reap the desired profit." Some British firms, he says, "appear to consider that an advertisement is in itself an oracle, to say nothing of it being in English," and he gives an illustration of British methods in Roumania worth quoting. For some time he has observed—his report is dated June 17, 1905—"a large and expensive advertisement in the main street of Galatz. Unfortunately there is no great demand for the advertised goods, as an inquiry by the firm at this Consulate would have revealed. But the still more unfortunate thing is that the advertisement, being in English, no one understands it. It still hangs on some rough palings surrounded by music hall notices and pictures of music hall singers. It has no connection with such matters, but more than one Roumanian supposed that it was a notice informing the public that a circus was coming from exactly where no one knew, and people went their way no wiser than when they came." The Consul says that no commercial travellers for British firms have called at the Consulate-General during the past two years in order to make inquiries. "There is no American Consulate at Galatz, but this has not prevented Americans travelling for American firms from coming to the British Consulate-General to make inquiries and seek advice."

California and Immigrants.—In his report upon the trade of California (No. 3433, Annual Series), Mr. Consul Bennett points out that before British subjects decide to come to California ordinary prudence requires that the conditions of the country shall be carefully inquired into. Farming in California is different from farming at home, and an experience gained on a British farm is not all that is required to make a successful settler in California. Numberless cases are recorded in the Consul-General's office where British subjects have purchased land in California that they have not seen, with disastrous results to the buyers. If people at home would stay a moment to consider, they would realise that if bargains are offered to them there is something wrong, as Americans on the spot are shrewd enough to pick up anything good on the market. "Land companies," writes the Consul-General, "are not all honest, even though they advertise their schemes in the best London papers, and especially in papers of a religious character, and even representations made in perfect good faith may on personal investigation turn out to be not quite what the reader at a distance thought them to be." The Consul-General advises (1) never to purchase land in California until it has been personally examined; (2) never to buy land at all until you have been in the country at least a year, and have learned all about crops, markets, labour supply, &c.; (3) never to pay a premium to learn farming; (4) take a berth on a ranch for a year or so whilst you look about and gain experience; (5) avoid land companies, land syndicates, and real estate agents; (6) satisfy yourself as to why Americans in large numbers and with considerable capital are leaving California for Cuba.

Industrial Hygiene.—In connection with an exhibition to be held next year at Milan, there is to be a competition of appliances to safeguard against accidents, and the folowing prizes will be offered:—A gold medal and £320 for a new device which will suppress the danger to life coming from a contact formed between the primary and secondary circuits of an electric transformer; a gold medal and £40 for a crane or hoist provided with a simple and practical device preventing the rotation of the cranks on the descent of the load; a gold medal and £20 for a simple, strong, and effective apparatus for automatically stopping cars which are moving upon an inclined plane in case the traction cable should break; a gold medal for a practical device for exhausting and collecting the dust formed during the sorting and cutting of rags by hand; a gold medal for an apparatus for localised exhaust and successive elimination of dust produced during the cardage of flax, tow, hemp, jute, &c.; and a gold medal for an effective device to prevent the diffusion of dust in places where the preparation of lime and cement is carried on. The competition is to be under the auspices of the Association of Italian Industries, and names of competitors must be sent to the Secretary, at Foro Bonaparte 61, Milan, before the end of the present month.—*Nature*.

NOTICES.

SECTIONAL COMMITTEES.

INDIAN SECTION COMMITTEE.

The following is the list of the Indian Section Committee, as appointed by the Council:—

Sir Owen Roberts, M.A., D.C.L., F.S.A. (Chairman of the Council).
Sir William Lee-Warner, K.C.S.I. (Chairman of the Committee).
Sir Frank Forbes Adam, C.I.E.
Lionel R. Ashburner, C.S.I.
Sir Athelstane Baines, C.S.I.
Sir Steuart Colvin Bayley, K.C.S.I., C.I.E.
Thomas Jewell Bennett, C.I.E.
Sir M. M. Bhownaggree, K.C.I.E., M.P.
Sir George Birdwood, K.C.I.E., C.S.I., LL.D, M.D.
H. M. Birdwood, C.S.I., M.A., LL.D.
Major-General Sir Owen Tudor Burne, G.C.I.E., K.C.S.I.
Sir Charles H. T. Crosthwaite, K.C.S.I.
F. C. Danvers.
Sir Charles A. Elliott, K.C.S.I., LL.D.
James Fairbairn Finlay, C.S.I.
Lord Harris, G.C.S.I., G.C.I.E.
Colonel Sir Thomas Hungerford Holdich, R.E., K.C.M.G., K.C.I.E., C.B.
Sir Philip Perceval Hutchins, K.C.S.I.
Sir John Jardine, K.C.I.E.
Sir Seymour King, K.C.I.E., M.P.
Henry Luttman-Johnson.
Sir Charles James Lyall, K.C.S.I., C.I.E., M.A., LL.D.
Sir James Broadwood Lyall, G.C.I.E., K.C.S.I.
Sir James Lyall Mackay, G.C.M.G., K.C.I.E.
J. M. Maclean.
General J. Michael, C.S.I.
Sir Patrick Playfair, C.I.E.
John David Rees, C.I.E.
Right Hon. Sir Joseph West Ridgeway, G.C.M.G., K.C.B., K.C.S.I.
Field-Marshal Earl Roberts, K.G., K.P., G.C.B., G.C.S.I., G.C.I.E., V.C.
Alexander Rogers.
Sir Edward Albert Sassoon, Bart, M.P.
W. S. Seton-Karr.
Sir Charles Cecil Stevens, K.C.S.I.
Colonel Sir Richard Carnac Temple, Bart., C.I.E.
Carmichael Thomas.
Thomas H. Thornton, C.S.I., D.C.L.
Sir Charles A. Turner, K.C.I.E.
Alexander Falconer Wallace.
Sir George Watt, C.I.E.
Sir Raymond West, K.C.I.E., M.A., LL.D.
Field-Marshal Sir George Stewart White, G.C.B., G.C.S.I., G.C.M.G., G.C.I.E., G.C.V.O., V.C.
Arthur N. Wollaston, C.I.E.
W. Martin Wood.
S. Digby (Secretary).

COTTAGE EXHIBITION AT LETCHWORTH.

The instructive exhibition of model cottages which the Duke of Devonshire opened on July 25 on the estate of the "First Garden City, Limited," and which has deservedly attracted much attention, owes its existence mainly to the inspiration of an article in the *County Gentleman*. The principal cause of the serious depopulation of the rural districts is, in the opinion of the writer of the article, Mr. J. St. Loe Strachey, the labourer's increasing difficulty in obtaining house-room. When cottages collapse from decay, very few houses of a similar class are built to replace them, owing, firstly, to the cost, and, secondly, to restrictive by-laws. The prosecution by a local authority in Sussex of Mr. Justice Grantham for erecting a cottage that infringed their by-laws, and the demolition of a bungalow erected by another well-known landowner in the same county, have brought the second of the obstacles prominently before the public. "The adoption of these ill-considered and coercive rules and regulations in so many parts of England has," says Mr. Strachey, "not only prevented cheaper cottages being erected within the areas affected by them, but has also checked the application to the manufacture of building materials of the inventive ingenuity and scientific knowledge which, had there been a free field in cottage building, would certainly have been applied to the solving of the cottage problem." Apparently, as a general rule, cottages are not allowed by the rural authorities to be built of other material than brick or stone. It is hoped that one result of the exhibition will be the ultimate abandonment of this narrow limitation. With respect to cost, Mr. Strachey remarks:—"At present a cottage in the country with a garden, which is essential, costs, not counting the land on which it is built, and making the smallest possible allowance for fencing and laying out the site and providing the water supply, at the very least £250, and probably more if the cottage stands by itself, and is not semi-detached or one of a row. But 4 per cent. on £250 means £10 per year; rates account for another pound, and insurance and annual repairs must be placed at at least a pound." Obviously the labourer cannot afford to pay more than £8. Is it possible to build a £150 cottage that can be let for such a rent? A £150 cottage might just be let for £8 a year, not counting anything for site or water supply, which usually, it may be supposed, would be

thrown in. But there is a consensus of opinion amongst landowners that a dwelling providing the necessary accommodation, cannot, under the existing restrictions, be erected for £150. The large and varied collection of houses at Letchworth is intended to show what can be done if the present by-laws are modified. The exhibition is independent of the Garden City now in process of gradual formation on an open, elevated and pretty situation in Hertfordshire; but the local building regulations are anything but restrictive, and the idea is to retain the various structures for permanent use. The cottages built for competition number over 70, of which 50 are single and the rest in pairs or groups of three and four. Numerous substantial prizes are offered both for the permanent buildings and designs, the latter being shown in the spacious sheds erected for the accommodation of the unemployed who were taken down from London for road-making. In the former category the first prize (£100) is offered for the £150 cottage, detached, and complying with the following requirements:—(1) Number of living rooms —one living room and scullery or kitchen-scullery. (2) Height of living rooms—not under 7 feet 6 inches. (3) Number of bed-rooms—three, with two fireplaces. (4) Height of bed-rooms—not under 7 feet 6 inches. (5) Cubic space in bed-rooms—2,000 feet. Class II. Best pair of five-roomed cottages (including scullery or kitchen-scullery) erected at a cost not to exceed £300. Class III. Best group of three or four cottages, cost not to exceed £35 a room. Class IV. Best detached cottage or pair of cottages, cost not to exceed £35 a room. The net cost in each case to be exclusive of architect's fees and builder's profits.

One of the points to be taken into consideration by the judges is durability, the importance of which in a climate like ours was insisted upon by the Duke of Devonshire in his eminently practical speech. The special correspondent of *The Times*, in describing the private view, suggests that the £150 standard has been too prominent, "The result seems to be that most of the architects and builders have laid themselves out to produce the prettiest thing they could for the money, not to produce a sound and serviceable dwelling for the lowest possible cost, which I understand to be the real object in view. The general impression is less of genuine labourers' homes than of tasteful little week-end or summer holiday cottages for town-dwellers whose means do not run to a country house, but who can afford a modest *pied-à-terre* amid rural surroundings. There is a great and growing demand for such cottages, and in some districts it is responsible for a good deal of the native displacement and for rising rents. The present exhibition contains many charming specimens which will appeal to persons of taste in search of a cheap and pretty rustic roof-tree, and no doubt it will stimulte building among that class. This is very well, but it is not the same thing as housing the rural population." Some who have visited Letchworth will be inclined to agree with this criticism, but certain of the cottages are plain enough for anybody, and, what is more important, there is no lack of variety in the materials employed. For example, one artistically conceived and admirably-arranged cottage is built principally of timber on concrete foundation, the "weather-boarding" being treated with carbolineum to prevent rotting. In the case of another exhibit the brick walls are covered with Portland cement and rough cast. Amongst the special prizes is one of a hundred pounds, given anonymously, for the cheapest cottage in the exhibition. consideration being had to its soundness and suitability for a rural labourer and his family. The area of the Letchworth property is extensive, close upon 4,000 acres, but the chief exhibits are conveniently grouped together in a spot near the Icknield Way, the ancient Roman road that extended from Yarmouth to Land's End, and quite near to the new station that has been recently opened by the Great Northern Railway on the main line from London to Cambridge.

The number of the *Building News* for July 28th contains a notice of the cottages erected at Letchworth with illustrations of several of them. The writer says that "in the opinion of Messrs. Parker and Unwin, who are acting as advisory architects to the Garden City Company, the problem is rather 'How cheaply can we build a good cottage?' than 'How good a cottage can be built for £150.' In their opinion, if a good cottage cannot be built for £150 there is no insuperable reason why the sum should not be increased to £175, this being merely a matter of 6d. per week adjustment in rent and wages." The writer adds, however, that this is the crux of the whole matter. "The labouring man is in this position:—that his employer will not under any circumstances pay him more than his present wage, while his landlord cannot let him his cottage at its present rental. The wage being already so low that no further economy is possible in clothing or in food, it is difficult to see how the extra sixpence per week demanded by the landlord is to be found."

The writer, referring to the materials used in the building of the cottages, says of Mr. V. Dunkerley, one of the exhibitors:—"He has used two new materials, employing the rapid and smooth-setting Pytho plaster for his wall surfaces, and asbestic bricks for his walls. These are composed of lime, sand and asbectic, and are machine-made and steam dried. They are made in many colours, and are hard and true of arris, and ring well." Of other materials, the writer mentions "expanded metal, wire-wove roofing, the mack partition, and uralite, while many of the houses are of timber construction entirely. All have red-tile roofs."

It is worthy of note that in 1863, when the Society of Arts offered special prizes for designs for cottages for the labouring classes, these prizes were "for the most approved designs for cottages with three bedrooms in each, to be built singly or in pairs, at a cost not exceeding £100 each."

DIAMONDS AND THE DIAMOND INDUSTRY.*

In 1475 Louis de Berquem invented the great art of diamond polishing, and in 1476 established at Antwerp the earliest known works for the purpose of cutting and polishing diamonds. The disturbed state of that part of Flanders drove the diamond industry to Amsterdam, where it flourished uninterruptedly for upwards of three centuries. It was not until the independence of Belgium was established in 1830 that Antwerp began to recover its position as the headquarters of the diamond industry. After the discovery in 1870 of diamond mines in Cape Colony, the wages earned by skilled workmen at Antwerp increased to so great an extent that some of the workmen are said to have earned wages amounting to as much as from £40 to £48 a week. Since that time the diamond trade of Antwerp has continued to increase in importance, and it now equals that of Amsterdam. The whole European diamond trade is centred in these two towns.

Diamond cutting is divided into three separate and distinct processes—(1) cleaving, (2) brutage, (3) cutting and polishing. Cleaving is the act of dividing the layers or scales which form the crystal, an operation which can only be performed in one manner on account of the flaky formation of the diamond. The stones have to be divided in accordance with the running grain of the carbon of which they are composed, and any attempt to divide them in another way would result in their being split and destroyed. A diamond is cleft as follows:—The rough stone is placed in a small metal receptacle, with the side of the diamond which it is desired to cut facing downwards. Over this receptacle is placed a shaped mould which is securely attached to it. Into the top of this mould is then poured liquid aluminium, which runs into the shape of the mould and, after being cooled, securely holds the diamond in the required position. The mould is then removed and the stone remains fixed in the aluminium ready to be applied to the cutting tool. The machine used for the cleaving is a small circular saw of about four to five inches in diameter, which rotates at a high rate of speed and is driven in the ordinary way by a leather belt from the running machinery. The saw itself is made of fairly soft copper with a prepared edge. To prepare the cutting edge of the circular saw it is necessary for it to go through a special process by which diamond dust mingled with oil is forced into its edge. "Diamond cuts diamond" as, after the preparation of the saw, its cutting edge is embedded with minute grains of diamond dust. The diamond is then applied to the saw in a similar manner to that in which wood is placed against a circular saw in a mill with the slight difference that the diamond is held immovable in an instrument overhanging the saw which presses it gently against the blade. It frequently takes two weeks continual work to cleave a diamond, the duration of the time depending entirely on the hardness of the substance of the stone to be cut. The most difficult stones to cut are those of double formation, the grain of which is interlaced, thereby creating greater resistance. The machine used was invented some years ago in America by a Belgian who was at the time working in the United States. Before its invention diamond dust for the finishing process was often most difficult to obtain, and manufacturers had frequently to grind fragments of inferior diamonds by means of a hardened steel pestle and mortar, but nowadays the supply of diamond dust is always abundant, not only "for the requirements of the factories, but even to be disposed of for use in other industries, such as glass-cutting." Before the coming into use of the machine referred to, the whole of the process of "brutage" had to be performed by hand, and was most monotonous and tiring work, the shaping of larger stones in particular necessitating a great loss both in time and labour.

The second process in the preparation of a diamond is its primary formation before it is ready for the first cutting and polishing, and the operation is carried out by means of mechanically rubbing one stone against another until the desired formation is achieved. Before the "brutage" takes place the stones are received either in their rough state, save that they have been washed clean, or else from the cleaning department in so many small pieces. The mode of procedure is as follows:—Two diamonds may be taken of similar size and equally hard in substance. Each stone is fitted into a brass or other metal cap by melting cement in a gas flame, which is then dropped into the aperture of the cap, the diamond being fixed in the cement, which is afterwards cooled and set by being plunged into cold water. Thus, two diamonds of equal dimensions are firmly fixed each in a separate metal cap or holder. One of these stones is then attached, by means of the cap which holds it, to a rotary machine, the stone forming the revolving centre. The other stone is fitted to a long handle or holder, and is placed against the revolving stone in the required position in a similar manner to that in which the tool is applied when cutting wood or metal in a lathe. The diamond dust which is produced by the rubbing of the stones together falls into a copper box called an "Eglisoir," or diamond dust box, which is placed immediately below the diamonds being worked. This dust is carefully preserved, and it is eventually used in the third operation of cutting and polishing.

Cutting and polishing is the third and last operation in the preparation of a diamond previous to its sale. In this process the stone, which has been roughly shaped by the second operation, is placed in position at the required angle in a copper holder with

* The statements of fact made in this paper rest upon the report of Mr. Consul-General Hertslet on the diamond industry of Antwerp, just published (No. 631, Miscellaneous Series).

which it is firmly pressed by means of a forked clamp, which is pressed against the stone and locked into position with a key. Great skill is required on the part of the workman in fixing the diamond into the holder. Many stones of one-eighth of an inch and less in diameter, weighing between 1 and 2 grains, have as many as 50 to 100 facets or separate cut faces, each at a different angle. Continual practice, however, facilitates this operation, and a skilled workman can immediately place the stone in the holder at the required angle ready for the cutting of another facet. When the stone is ready in the holder it is placed against a revolving disc of soft steel rotating in a horizontal position at a speed of some 3,000 revolutions a minute, and is left there until the required facet is cut and polished. The surface of this disc is prepared with a mixture of diamond dust and purified olive oil, which is rubbed into the steel, and it is this dust, which comes in the form of waste from the second operation of "brutage," that effects the polishing of the stones.

In olden times diamond cutters contented themselves with cutting as large a number as possible of small facets on the surface of a stone, regardless of regularity, and without taking into account its form or size, but it is now recognised that to obtain the best results and sparkling glitter, a diamond must be cut in a regular form, so that one surface may reflect on another thereby showing forth the hidden light and beauty of the stone. There are two common forms of cutting diamonds, it may almost be said there are only two forms, the brilliant and the rose, the brilliant for stones of a certain uniform thickness, and the rose for flatter stones and layers which have been cut from other and larger diamonds. The cutting of a brilliant is the process which best shows forth the lights and reflections contained in a diamond. A perfectly formed brilliant should have the proportions in depth from the upper surface or summit to the lower point called the pyramid or pavilion of two-thirds of the diameter of the stone at the belt or middle. The summit, or crown, of a brilliant should have 32 facets, and in addition one large central facet called the table. From the side of the pyramid it should have 24 facets and one small facet at the lower point called the "colette," making in all 58 facets, and not, as has sometimes been stated, 64 facets. These facets should be calculated, divided, and regularly cut in such a manner that those cut on the pavilion of a diamond may reflect the light on to the facets cut on the summit, and *vice-versâ*, thus showing forth in as high a degree as possible the sparkle and glitter of the gem. All diamonds are cut in a series of stars, one being formed over the other. On looking through the flat surface, or table of a properly cut brilliant the "colette" or lowest point should appear to be directly in the centre of the table. In the regular cutting of these facets depends the whole beauty of a diamond, and in their formation lies the secret and difficulty of the diamond trade. The rose is a more usual form of cutting diamonds, of less value and thinner formation, and is cut with one large facet at the base and 24 triangular facets on the summit. The thicker stones cut in this manner, with 24 facets, are called on the Continent "Roses Couronnées." Those which are only cut with 12 or six facets are known by the name of "Roses d'Anvers," and form one of the chief specialties of Antwerp. The quality and value of a diamond may be roughly determined by examining it against the light. In a stone of inferior value there appear to be many lines or scratches, whereas the more perfect stone is recognised by its purity and lack of marks in the grain, and also by its regularity of formation.

The bulk of the diamonds worked in Belgium and the Netherlands originate from British possessions, or mines owned by British subjects. The diamonds, after being cleaned and weighed in their country of origin, are sent to merchants in London, where they are sorted and put up for sale. The stones are then invariably purchased by foreign merchants who have their factories abroad. Thus although the stones come first to the United Kingdom, they are afterwards conveyed abroad to be cut and prepared, and then in many cases returned to the United Kingdom to be sold by retail dealers. By this practice the whole of the diamond industry, with its profits, is lost to the United Kingdom. It can hardly be said that low wages prevents British competition in the diamond industry. The average wage paid to diamond workers at Antwerp range from £2 12s. to £2 16s. per week. The diamond cutters are paid from £2 8s. to £3 4s. per week, the shavers from £4 per week upwards, and the sorters are paid wages varying from £1 5s. to £2 per week. The workers employed in all the branches of the industry at Antwerp, number from 4,000 to 5,000, including some 70 women employed on the lighter work. No precautions are, or can be taken, to guard against dishonesty in the workers, but cases of dishonesty practically never occur. It is difficult to state the names of the countries to which diamonds cut at Antwerp, are sent, or the value of the stones exported, as no statistics on the subject are published. A diamond is so small an object, and one of so great value, that practically all the diamonds exported are sent out of the country without the knowledge of the Customs officials. In the Customs returns for 1903, is a note which states that owing to the existing conditions of the export of cut diamonds it is impossible to give details of their value, but that from information received, it is estimated that the value of the exports during that year amounted to £3,340,000. Precious stones are admitted free of duty in Belgium, and there seems to be no sufficient reason why this valuable industry should not be carried on in the United Kingdom. It ought to be possible for the British workman to learn the art of diamond cutting in spite of the secrecy adopted by the diamond cutters as to their method of working.

THE SOUTH WALES COALFIELD.*

A good deal has been said during the past two weeks regarding the reported acquisition by a German Syndicate of a steam coal area in South Wales. Many of those who have said so much would have done better to make themselves acquainted with the actual facts of the case. Fortunately this is a very easy matter. In a supplemental report issued some time ago by the Commission on Coal Supplies, and printed in the *Iron and Coal Trades Review*, the subject of the South Wales coalfield—one of the largest, and, having regard to its extent, the quantity and unequalled qualities of the steam coal, it contains the most important of the coal resources of this country—has been most ably and completely dealt with by Sir William T. Lewis, a member of the Commission, who unquestionably, from his prominent position as a colliery owner, his acknowledged eminence as a mining engineer, and his intimate knowledge of this great coalfield, was best qualified for the important work entrusted to him by the Commission. There are separate reports which deal with the relatively small and neighbouring coalfields of the Forest of Dean, Somersetshire, and Bristol, but I shall confine myself to the South Wales coalfield, and more especially to that portion of it in the county of Glamorgan, from which, as will be seen from one of the tables in the report, nearly 70 per cent. of the total annual coal output of the coalfield is at present derived, nearly half of which (47·31 per cent.) is shown to consist of steam coal.

The discovery of these steam coal seams, which has led to the enormous development of the Welsh coal industry during the last 33 years, and which has made Cardiff what it now is—the chief port of export in the kingdom—is well worthy of mention, and has a direct and important bearing upon the question of the duration of our coal resources.

Speaking from my own knowledge and long experience of colliery working in Wales, I should, in the first place, mention that the coal seams previously almost exclusively worked were the upper and bituminous coal measures. The coal obtained from them, other than that used for domestic purposes, was ordinarily converted into coke for blast furnaces, and nothing but coke was then, by statute, allowed to be used for locomotives on account of its smokeless character. Many English and French railways were then supplied with coke from the Welsh collieries, some of the colliery owners having their own coke ovens at Nantes and other French towns, and the coal being sent there to be coked.

As regards the discovery of steam or "smokeless" coal, as it was termed, the following were the circumstances as narrated to me at the time by the late Mr. John Nixon, to whom, in a great measure, we owe the development of the coal industry and the first introduction of Welsh coal into France and other foreign countries. He told me he was then the agent in France for one of the Welsh colliery owners, and, happening to be in London and on board one of the Thames river steamboats, he noticed the engine-man looking up at the funnel of the steamer and shouting down to his mate below, "No smoke." Failing to learn the cause of the "no smoke," Nixon succeeded by tipping the engine-man a half-sovereign in ascertaining that he and his mate were testing some "smokeless coal," as he termed it, obtained from some unpronounceable place in Wales, and, after satisfying himself as to its smokeless character, Nixon said he visited the locality whence it came, and found the coal was obtained from one of the many fine steam coal seams, now well known to underlie at great depths the upper and bituminous seams already alluded to. The pioneers, however, in the working of steam coal, and who first introduced it for steam and other services to London, were the Thomas family, of Waunywllt, the unpronounceable place alluded to in Nixon's story.

In Sir William Lewis's report full particulars are given of these steam and other coal seams, with a table giving their varying number and aggregate thickness in different parts of the coalfield. In the county of Glamorgan, from which, as already stated, about 70 per cent. of the total annual output of coal of the entire coalfield is at present derived, there are, in some parts of the coalfield, as many as 42 seams, with an aggregate thickness of 124 ft. 6 in. of workable coal; in other parts 67 seams, with an aggregate thickness of coal varying from 94 ft. 6 in. to 84 ft. 10 in.; 52 seams, with an aggregate thickness varying from 70 ft. 11 in. to 66 ft. 8 in.; and 14 seams, of an aggregate thickness of 65 ft. 11 in. The exact average aggregate thickness of the coal seams in all parts of the county (taking into account the number of each group of seams) is 91¼ feet of workable coal, while the average aggregate thickness of the coal seams throughout the entire coalfield is exactly 78 feet, irrespective, however, of the extent of each coal-bearing area.

Although the number and aggregate thickness of the workable coal seams in different parts of the coalfield as shown in the report afford a very good idea of the great extent of the coal resources of the Glamorganshire portion of it, they do not, in the absence of the necessary information as to the extent and position of the respective coal-bearing areas, enable the quantity and average aggregate thickness of the coal seams throughout the entire coalfield to be correctly ascertained. The table given, however, affords a striking illustration of the extreme care and judgment shown in ascertaining the correct coal-bearing areas throughout the entire coalfield. A comparison of the 78 feet average aggregate thickness of the coal seams as obtained from it (irrespective of the extent of the various coal-bearing areas) with the actual average thickness

* Article by R. Price-Williams, from the *Iron and Coal Trades Review*.

of 37·21 feet* as deduced from the statement in the report that the total area of the coalfield is 1,000 square miles, or, in other words, 640,000 acres, and that an acre of coal 1 foot in thickness represents 1,500 tons of it, shows that the 35,723 million tons of coal estimated in the report as remaining unworked in this coalfield owing to limitations in the coal-bearing areas, has had its average aggregate thickness of seams reduced to the lesser figure.

Accompanying the report there is an excellent geological map showing the extent of the coalfield, with the position marked upon it of a number of sections of typical strata, and showing the number, depth, and thickness of the different coal seams. The extent of the let and unlet coal areas has also been carefully ascertained, and with all this valuable data and a great deal more derived from an intimate knowledge of this great coalfield, Sir William Lewis has furnished the Commission with a most valuable and reliable estimate, from which it appears that the total available coal resources of the entire coalfield, after making full allowance for loss in working, due to coal left underground, faults, and other causes, including a deduction of 5 per cent. for consumption in raising the coal are, roundly speaking, 26,919 million tons, or considerably more than one-fourth of the total available coal resources of the United Kingdom.

As a striking illustration of the magnitude of these coal resources it is pointed out in the report that, taking the output of 364¾ million (364·72) tons during the last ten years (1894-1903, inclusive) as a measure, it would take 738 years with that maximum decennial output to entirely exhaust them. These figures, however, are obviously not put forward as an estimate of the probable duration of these large coal resources, inasmuch as side by side in the valuable table of the annual outputs of coal in the entire coalfield the average rates of increase during the last 33 years are most correctly given, from which it appears that the decennial rate of increase varied during the last 30 years from a maximum of 56·23 per cent. per decade, or 4½ (4·56) per cent. per annum to 31·1 per cent. during the last decade, or 2·34 per cent. per annum. The average rate, however, during the whole period of 33 years was as much as 41·31 per cent. per decade, equivalent to 3½ per cent. per annum, a rate which, if maintained, would exhaust the whole of the available 26,919 million tons of coal in considerably less than 100 years, as the total output of coal during that period as calculated at that rate would be 35,271 million tons.

The average rate of increase of the total output of coal does not, however, give anything like a true idea respecting the different classes, the output consisting of two distinct items, home consumption and export coal, each differing largely in quantity and in rate of increase.

The export coal is not given separately in the Tables in the report, owing to the fact that the ports of export for the coal outputs from some of the counties are indeterminate. I have, however, been able to ascertain from the annual coal export Tables given in the appendices to the report of the Commission (Part XI.) the annual coal exports from the ports of the entire coalfield, and also from the Glamorganshire ports, from which county alone, as already stated, 70 per cent. of the coal output is derived, and I have prepared a Table showing the home consumption and export coal separately, with their respective rates of increase during the 33 years dealt with in the Tables in Sir William Lewis's report. The results obtained are very striking, and afford all the requisite data for correctly ascertaining the past average rates of increase and the decrements in those rates during the period in question of both the home consumption and export coal.

Although, as in the case of the output of coal in the United Kingdom, the rates of increase of the home consumption and export coal differ greatly, I find the decrements in the respective rates have, during the period dealt with in the report, been exceptionally large, more especially in the Glamorganshire portion of the coalfield, which with portions of Carmarthenshire and Breconshire contain nearly 90 per cent. (89·71 per cent.) of the total resources, and produce 70 per cent. of the annual coal output of the entire coalfield. The home consumption coal, in this portion of the coalfield, has of late been increasing at a comparatively slow rate, and in quantity it is now largely exceeded by the export coal, which more than trebled in the first two decades, and, although still increasing, is doing so at a much less rapid rate. It is, in fact, the exceptionally large decrements in the rates of increase of both the export and home consumption coal which constitute the remarkable and most hopeful circumstances in connection with the future duration of these coal resources, inasmuch as their continuance, in spite of the large increase in the coal exports, would, as the following brief tabular statement shows, result in prolonging the duration of the coal resources in this portion of the South Wales coalfield, which contains the great bulk of these precious seams, for at least three centuries and more, beyond the period of 100 years and less, which (with the continuance of a constant rate of increase of output of 3½ per cent. per annum) would inevitably witness their complete exhaustion. I would add that the effect of these exceptionally large decrements in the rates of increase, mainly due, as already stated, to greater economy in the working and consumption of coal, would be to reduce the rates of increase to a nominal figure, in the short space of a hundred years, as shown in the statement. There appears, therefore, to be everything to justify the belief that with the further important economies which the Coal Commission consider practicable, there will be no actual decrease in the coal output in this portion of the coalfield for a much longer period.

$$* \frac{35{,}723{,}000{,}000}{640{,}000 \times 1{,}500} = 37{\cdot}21146 \text{ ft.}$$

SUMMARY OF FUTURE COAL-OUTPUTS IN GLAMORGANSHIRE.

—	Rate of increase per decade 1890–1899 = 13·96 per cent. Average decrement = 40·63 per cent.	Rate of increase per decade 53·83 per cent. Decrement = 48·31 per cent.	Total output.
	Tons.	Tons.	Tons.
1st century	1,327,482,200	1,912,734,000	3,240,216,200
2nd ,,	1,364,859,500	2,023,725,000	3,388,584,500
3rd ,,	1,364,859,500	2,023,725,000	3,388,584,500
4th ,,	1,364,859,500	2,023,725,000	3,388,584,500
	5,422,060,700	7,983,909,000	13,405,969,700

In conclusion, I would point out that, although the total quantity of coal calculated to be worked out in the Glamorganshire portion of the coalfield (in the event of these large decrements in the rates of increase of output being maintained) only amounts to about half the total available coal resources of this portion of the coalfield, the quantity, by a mere coincidence, is almost exactly what Sir William Lewis estimates as the total available amount of our Welsh steam coal resources, viz., 13,407 million tons. It is, however, to be hoped that in what will remain of the available coal resources in this portion of the coalfield, when that half has gone, the greater portion will consist of steam coal.

THE MANUFACTURE OF COGNAC BRANDY.

Pure cognac brandies are distilled from wines produced in the Cognac region, the Charente and Charente Inférieure, and are classed in quality by the district from which the wine comes. There are the "fine champagne," the "petite champagne," "borderies," "fins bois," "bois ordinaires," and "bois communs." The "fine champagne" is grown in a district of France directly to the south of Cognac, comprising half a circle, of which Cognac is the centre. The "petite champagne" is grown in a district which would be enclosed between the first half-circle and a larger one paralell to it, at a distance of several miles. The "borderie" is produced in a triangular portion of territory immediately to the north, and slightly to the west of Cognac. Surrounding these areas, but extending a greater distance to the west and to the east, is the region in which is produced the "bois ordinaire," while the "bois commun" is produced between the last-mentioned district and the coast, directly to the west and the south-west. The "bois communs" are also produced on the islands of Ré and Oléron. The wines are distilled under three different auspices. (1) By the "bouilleur de crue," a vineyard owner who distils his own product and sells it to the manufacturer. He usually possesses one still and sometimes two. (2) The "proprietaire," who distils his own product and that of his neighbours, from whom he may buy the wine, or for whom he may distil for remuneration in kind. The "proprietaire" may possess four to eight stills. (3) The "merchant" who owns many important distilleries, wherein are reduced to brandy the wines from his own vineyards and purchased wines. When the wine is bought, the producer is paid in accordance with the degree of alcohol contained. The merchant may have sixteen or even twenty stills in each of his establishments, with a capacity for reducing 40,000 to 50,000 hectolitres (880,000 to 1,100,000 gallons) of wine into brandy during the season.

The methods of distillation vary greatly with the kind of wine, the district, and the person who has charge of the distillery. The United States Consul at La Rochelle says that, as a rule, all Cognac wines are distilled with the lees. The stills employed in the champagne district are usually simple pot stills, with or without "chauffe-vin." The simple still consists of the "choudière," or boiler, the "chapiteau" which connects the boiler with the third part, and the condenser with its serpentines. The "chauffe-vin" is supposed to be an improvement on the simple still, by which several hours may be saved on each operation. It consists of a reservoir connected with the boiler, through which passes the pipe of the "chapiteau" containing the hot vapours of the wine, which warm the wine to a degree just under that necessary to produce vapours in sufficient quantity to be condensed. Consequently, when the boiler is emptied it can be refilled at once with wine at a temperature high enough to begin to give off vapours at once when over fire. The boiler is filled with wine by means of a pump, if the still has no "chauffe vin," and from the "chauffe vin," if having one. The boilers contain usually about 500 litres (110 gallons) and the liquid is evaporated by an urn, but mild heat, which is continued until the alcoholometer indicates that the distillate contains O alcohol. At this time it is found that from one-fourth to one-third quantity of wine has passed through the condenser and this distillate is called "brouillis."

In the small distilleries, a still is filled three times before enough brouillis is obtained to commence its redistillation. In the larger distilleries the products from three stills are united in a single still, and another or second distillation commences, by which the brouillis is converted into brandy. This is called la "bonne chauffe." The "bonne chauffe" is divided into three or four sections as follows:—Five per cent. of liquor which leaves the still possesses a highly disagreeable odour, due to excessive quantities of concentrated aldehydes and acetic ethers, of a colour often greenish or white called "la tête," or heading, which is taken into a receptacle and kept apart from that which follows. The quantity may exceed five per cent., depending on the nature or quality of the wine. These headings are later mixed with another brouillis, or with what is called "seconds." This alcoholic heading, in condensing, has washed the interior of the serpentine

and has removed certain oily matters which remained in the spiral from the preceding distillation. The part of the distillate which follows, known as the "cœur," or heart of the "bonne chauffe," is clear, and consists of from 80 to 85 per cent. of alcohol. The "cœur" continues to run into the same receptacle until the alcoholometer indicates that the liquor leaving the still contains 50 per cent., or perhaps 55 per cent., of alcohol, according to the wine. When properly carried on, this process lasts about eight hours, and the liquid contains from 66 to 70 per cent. of alcohol. This product is brandy. The distillation, however, is continued until again the alcoholometer registers O alcohol. The product of this third part of the distillation is called "queue," or tailing, and is generally added to the next lot of wine placed in the still. It contains from 20 to 24 per cent. of alcohol. Sometimes, however, when the wine is very rich in alcohol a fourth is produced, which is known as "seconds," and consists of that part of the operation wherein the distillate reduces its strength from 60 to 20 degrees. These seconds are usually added to the next brouillis, while the remainder of the alcohol obtained—that is, from 20 degrees to O, which in this case is the tailing—is mixed with the next batch of wine. The seconds require about four hours of distillation, which makes the entire process last about twelve hours. This length of time of course applies to the "bonne chauffe." The quality of the brandy produced may depend very largely on the purity of the copper, of which the boiler, "chapiteau," and serpentine is composed, as it has often been remarked that the oily acids attack the metal and bring away in the distillate very perceptible quantities of copper compounds, which are disagreeable to the taste and are probably dangerous to health. Length of time taken may also mean much. Wine distilled too rapidly may force its fumes too quickly through the serpentine to be condensed, and consequently some of the elements most volatile may escape. Again, the point where the heart is separated from the tailing during the "bonne chauffe" may influence the taste and quality of the distillate. Certain of the superior alcohols pass earlier in the evaporation and the others later.

There are also what may be described as compound stills. These were invented with the object of producing brandy direct from wine in one operation or distillation. The principle of all these stills is that of a "chauffe-vin" and boiler combined, in such a manner as to obtain the complete condensation of vapours which leave the boiler, thus producing a brouillis, which in its turn is re-distilled. The condensation is generally effected by the "chauffe-vin," and the brouillis is collected in another or secondary boiler, in which is enclosed the larger one. The heat, which is furnished by the alcoholic vapours of the boiling wine, produces a distillation of the brouillis, the vapours of which in their turn, are sent into the serpentine and condensed into brandy. There are very large numbers and varieties of these compound stills, which are used only in the country of the "bois," where wines contain very much less aroma, and have a peculiar taste which is called "terroir," or savouring of the soil. The brandies produced from the bois wines, are usually mixed or blended with the highly aromatic brandy of the "champagne" or of the "borderies" districts. Much might be written descriptive of the various compound stills, which although unchanging in principle, becomes more and more complicated as distance increases from Cognac, the centre of the brandy trade. The most complicated ones are used in the districts of the "bois communs," and especially in the islands of Ré and Oléron. The United States Consul give the following description of the method of distillation as practised at one of the most important distilleries he visited. The boilers were filled twice in twenty-four hours. In the morning, half of the sixteen stills were filled with wine, and had produced by evening the impure alcohol known as the "brouillis" or "flegme." In the evening all the boilers were filled with wine, and the next morning they had produced the brouillis. All of the brouillis collected the evening before, and the morning following, from twenty-four different stills, is divided, and placed in eight of the sixteen stills, and is submitted to a re-distillation or rectification called "doubling." The other stills are filled with wine, as on the morning of the day before, in order to combine the process regularly and without interruption in the same manner during the entire season. By this system each man is charged in the morning with the filling of one boiler with brouillis, and one with wine; in the evening two boilers with wine. This idea is the direct result of the quantity of brouillis produced by the distillation of wine, *i.e.*, one-third so that three boilers must be filled with wine and distilled by each man in order to have sufficient brouillis to fill a single boiler and commence its rectification. Each time a still is filled and each time its product is obtained, whether brouillis or brandy, a declaration is made upon a register which is kept continually at the disposition of the Government régie. Each barrel of wine before it goes to the still is numbered, and the still into which it goes must be known; its degree of alcohol is also inscribed in duplicate on a register, one copy of which is placed in a box of which only the officials of the régie have the key; the other copy remains on the register. The amount of brandy produced from that particular barrel of wine must be in proportion to its alcoholic strength, and a register of the quantity obtained in brouillis, is kept in the same manner as for the wine. When the brouillis in its turn is distilled, a corresponding record is kept of it, and of the brandy which it produces. The products are placed in casks, each of which is numbered, and the quantity and strength of alcohol therein is also indicated on the barrel. This alcohol cannot be removed from the premises, neither can any

alcohol be brought to the premises or carried from one portion of a town or city to another without a permit from the régie, of which permits careful records are kept. The permits indicate by their colour, white or pink, whether the alcohol represented by them is wine or some other source than wine. It can be readily understood that this system renders the manipulation of alcohol exceedingly difficult to persons who desire to use it, and conceal the fact. The residues of the wine which is left in the still, after the brouillis has been produced may be used for the manufacture of fraudulent liquors, but at Cognac it has been found recently that it is much more profitable to denature these residues with lime in order to produce tartar salts, which contain from 48 to 52 per cent. of pure tartaric acid. Formerly, when the vintages were very small, owing to the ravages of the phylloxera, many irresponsible people added to the wine they distilled, rectified spirits produced from beets. The large quantities of wine produced in the last four years make this proceeding practically useless from a financial point of view. It is further rendered exceedingly difficult by the new regulations of the French Government represented by the régie.

THE HOUSING QUESTION IN GERMANY.

The housing question in Germany presents much the same problem for solution as in the United Kingdom. The migration of the people to the towns consequent upon the growth of trade has increased enormously the population of the towns, especially of those with more than 100,000 inhabitants, and housing accommodation has not been equal to the demand. Thus in April of the present year there was, says Mr. Consul-General Oppenheimer in his report on the trade and commerce of Germany just issued (No. 3,445, Annual Series), in Frankfort, 133 single room lodgings available for 554 applications, so that not even one-fourth of the demand could be satisfied. The disproportion between demand and supply of apartments of two rooms was even greater. Only one-sixth of the demand could be met, and in the case of three-room apartments half the number of applicants only found what they sought.

The annual increase in the population of Germany numbers 800,000. These, as well as those already in existence, must be housed properly, and most of them must be housed cheaply. The rapid increase of the population has caused a rise in rents generally, so that as with the similar classes in the United Kingdom, the poorer classes are spending a constantly increasing percentage of their income in the payment of rent. Delay in the solution of the housing question is dangerous in so far as it complicates the possibility of any remedies, for space is limited, and as far as it is required for cheap housing difficult to replace once opportunities have been missed. What were suitable and available sites only a few years ago have been bought up by the speculative builder, who has produced luxurious houses along luxurious streets. Then the prices of building materials have risen, wages are higher, and the value of sites has increased. The Imperial Treasury has spent 15,000,000 marks since 1901 for the purpose of providing housing accommodation, but this expenditure was practically limited to cheap apartments supplied for Imperial officials at low salaries. The Home Office has in some instances encouraged the building of small apartments by letting sites on prolonged leases (Erbbaurecht) at reduced rental under the condition that artisans' dwellings be erected, but often, as in the case of Schömholzer Haide, in the north of Berlin, it has disposed of Treasury lands to builders and others at the best possible price though suitable for cheap lodgings, and has thus missed rare opportunities. Many of the large factories have spent great sums in supplying their workmen with lodgings, often model dwellings. In some instances the area covered by such dwellings practically equals that of large villages, as in the case of the chemical works at Höchst, but the objection to the system lies in the fact that the tenancy ends with the contract of labour, and the workmen are thus easily robbed of the possibility of an independent attitude in questions arising between employer and *employés*.

In some parts of Germany building societies of a charitable nature were started with the purpose of building cheap dwellings for the workmen. Thus in Rhenish Prussia there exist 117 such building societies. The number of houses supplied by the societies amounted, up to April 1904, to 4,242, containing 9,020 lodgings; 62·5 per cent. were built for sale, the others for letting. Both kinds were chiefly built on the plan of admitting two families. The rents are on an average 20 per cent. cheaper than the ordinary local rents. In the houses for sale the workman live more cheaply too after the deduction of the payments made to capital account. Yet the financial position of the societies is in most cases satisfactory—71 of them paid an average dividend of 3·2 per cent. If the 9,000 families thus housed are on the average calculated to consist of five persons, 45,000 to 46,000 persons in Rhenish Prussia owe to these building societies healthy and clean houses, from which there is small danger of ejectment, and where there is no fear of increased rents. But it was only when a Bill was put on the table of the present Diet that an attempt was made to provide a remedy uniform for the whole kingdom.

The bill in one of its parts devises means to remove the causes which have so far deterred the builder from erecting small lodgings. The speculation in sites which is the chief reason of the present high rents is rendered impossible by provisions concerning the planning of the streets, the building plans, the frontage line, &c. Whereas the present building plans generally favour deep sites, very wide streets,

and consequently buildings, with a great number of apartments and courtyards, the new building plans are to be devised on a footing corresponding to the requirements of the district, so that quarters that are suitable for small lodgings shall be mapped out in shallow sites and streets of lesser width. As an inducement to the building of small lodgings the contributions towards the road-making are to be considerably reduced in all cases in which healthy and appropriate lodgings are built for the housing of families of small means. Another part of the Bill regulates the police intervention in the case of bad and crowded apartments. In communities of 10,000 inhabitants and more, it is proposed to compel the police to frame lodging bye-laws, and to give them power to frame such bye-laws for communities with less than 10,000 inhabitants. These bye-laws must regulate air-space, the separation of the sexes, the sleeping accommodation of *employés* and servants, &c. Provisions are also made for the inspection of lodgings by special officials, the communities with more than 10,000 inhabitants being forced to appoint a Lodging Board, consisting of competent persons, to carry out such inspection. Thus the Bill tackles the housing question from three different points:—(1) By means of building plans and building regulations; (2) by means of reduced taxation; (3) by the introduction and supervision of minimum demands concerning hygiene and morality. It is thought, however, that it does not go far enough. The provisions for cheapening of lodgings are considered by many to be insufficient; the reduction in the contribution towards road-making is considered inadequate inducement to the builder; it is held that the lodging bye-laws should be made compulsory in all communities instead of permissive where they do not number 10,000 inhabitants, and the question of windows has been entirely ignored. Yet the importance of this question of light may be gathered from the fact that in 1900 Berlin counted 24,000 so-called "cellar lodgings," so that 5 per cent. of its inhabitants were then lodged in cellars. There is nothing to show that the percentage is much lower in 1905.

AN INDUSTRIAL REVIEW OF NEW SOUTH WALES.

Among the varied information contained in the various statistical returns of the self-governing colonies few are of greater value than those figures which deal with the internal wealth of a country and the employment—agricultural or manufacturing—of its population. The Government of New South Wales in its Statistical Register for 1903* is no exception to the rule followed in certain of the colonies, but not in the Mother Country, of collecting information as to wages paid in factories or mining industries, and publishing these together with returns of the wages paid, and value of output.

* Published by William Applegate Gullick, Sydney, N.S.W. 1905. Price 5s.

Primarily, of course, New South Wales is a food-producing country, and first place must, therefore, be given to Part IV. of the Register to *Agricultural matters*. In agricultural pursuits 65,213 males and 5,948 females find employment. The preparation of dairy produce provides occupation for 15,208 males and 12,331 females. Pastoral pursuits engage a population of 26,051 persons, making a gross total of 124,751 persons engaged in work of a food-producing character. The value of the principal crops in 1904 amounted to £8,358,924, of which nearly one-half or £3,974,840 represents the value of the wheat grown. Second place is taken by hay of a value of £2,121,934, maize coming third, with crops to the value of £712,160. The value of implements and machinery in use on farms during the year ending March 31st, 1904, was £2,368,072 of farming machinery, £300,107 of dairying machinery, while £710,885 is returned as the value of machinery and implements (the latter sometimes agricultural) on pastoral holdings. As regards live stock, there were 458,014 horses, 1,880,578 horned cattle, and 26,656,501 sheep. Compared with 1901, there is an all-round fall in numbers due to the severe recent drought. The number of horses was then 486,716, of horned cattle, 2,047,454, while the number of sheep were 41,857,099. The drought period was a time of heavy wool and meat exports, the net exports of wool in 1901-02 being 759,536 bales, as against 508,990 bales in 1903-04; the weight and value of the frozen meat exported fell from 513,993 cwt., valued at £585,691, in 1901, to 146,226, valued at £206,160, in 1903. The quantity of butter made in 1903 amounted to 38,727,107 lbs., a quantity only once exceeded. Cheese was made weighing 4,748,176 lbs.—the largest quantity for nine years. The weight of bacon and ham was much less, being 7,864,771 lbs., as against about 9,000,000 lbs. and 11,000,000 lbs. in the two preceding years. Even the total production of milk is enumerated, the yield being about 130 million gallons. Of this about 10 per cent., or 12½ million gallons, was used directly on the farms for butter making; about 2 per cent. was used similarly for cheese making. About 75 per cent. was separated or sent to creameries or factories, the balance being used on the farm or sold for other purposes.

Apart from the population engaged in purely farming pursuits, factories for dealing with the farm produce and farm factories which have separate staffs afford employment for a total population of 28,659 persons. The value of the machinery and plant used for this purpose amounted to £516,155.

Mining.—In any consideration of the mineral wealth of New South Wales first place must be given to gold. The number of persons employed was 11,247, of whom 391 were Chinese engaged in alluvial mining. The value of the plant in operation at the mines was £953,970, the quantity of gold produced being 295,778 ounces, valued at £1,080,029. However, in regard to the value of the output, first place as regards value is taken by coal, of which

6,354,846 tons were mined, and were valued at £2,319,660. The value of the plant and machinery used in coal mining is returned as £1,770,312. Next in importance comes silver (lead and ore), of which 349,064 were produced, these being valued at £1,387,648. The total value of the minerals produced was 5,912,671, being a nett gain of £834,583 over the value in 1902. The production of tin and also of copper was in excess of that during any preceding year, the value of the tin produced by 2,502 miners being £155,723, while 1,816 persons engaged in copper mines produced copper and regulus to the value of £446,286.

Manufactories and Works.—In all 65,633 hands (of whom 52,453 are male, and 13,180 female) are employed in 3,476 establishments. The aggregate capital value represented by the machinery and plant is estimated at £7,009,806. The total sum paid in wages in 1903 amounted to £4,839,557. The industries are grouped under nineteen main headings, these headings being subdivided, and detailed information given in each case..

External Commerce.—The imports during 1903 amounted to a gross total of £26,770,169, of which £12,792,252 was composed of trade with other colonies forming the Australian Commonwealth, £6,651,820 with the United Kingdom, as £1,875,653 (which includes £1,001,300 from New Zealand) from the rest of the Empire. The total from foreign countries amounted to £5,450,464, to which the United States of America contributed £2,779,590, Germany £1,828,105, and France £1,733,593. A total Customs revenue of £2,9c2,687 was collected on these articles. The total value of the exports in 1903 was slightly larger than the imports, being £26,738,111. The exports are divided into three main classes—(1) that of New South Wales produce, (2) re-exports of other Commonwealth produce, and (3) re-exports or other produce. Broadly speaking, near £7,900,000 sterling was the value of the total exports to all Australian colonies; of this about £6,010,000 was locally produced. To the United Kingdom the total exports amounted to £7,560,000, of which £5,866,000 was produced locally. Other British possessions received £3,306,379, of which £1,106,610 was produced in New South Wales. The total sum of the exports and re-exports to countries within the Empire amounted to £18,743,036. The total sum of exports and re-exports to other countries only amounted to £7,995,075, of which the United States took £1,928,299, Germany £1,947,375, France £1,866,487, and Brazil £1,025,348.

BRITISH TRADE IN RUSSIA.

Mr. Consul Grove's Report on the trade of Moscow in 1904 (No. 3441, Annual Series), shows that the United Kingdom is losing ground in its business relations with Russia. Take mill and other machinery excepting agricultural. From 1901 till 1903, the ratio—roughly 1 to 2½ of the import—from the United Kingdom as compared with that from Germany was approximately the same, but in 1904, whilst the import from the United Kingdom decreased by some 900,000 roubles, that from Germany increased by 1,400,000. The same results are seen in other parts. In 1901 the value of the import of iron and steel goods from the United Kingdom was 1,491,000 roubles, as against 5,230,000 roubles from Germany, their respective figures for 1904 being 1,138,000 and 5,021,000. So with wire and wire goods. The imports from the United Kingdom in 1901 were valued at 740,000 roubles, from Germany 3,095,000; in 1904 the respective figures were 653,000 and 3,231,000. Now that the Russian Government has permitted the establishment and official recognition of *bureaux de renseignements* as to the status, &c., of Russian firms, the complaint of British commercial travellers that they can find out nothing as to the status of firms should shortly be a thing of the past. From her geographical position Germany is naturally greatly interested in the Russian market, but Mr. Consul Grove says that "there are very many Russians who would sooner deal with the British manufacturer if they were sure of obtaining equal inducements to those which the German offers, such as long credit, special consideration of local taste, quotations in Russian weights and measures, coinage and language—whereby is undoubtedly facilitated the transaction of business." Against this Mr. Grove says he can show hundreds of British catalogues sent to him annually in English, "with the national, and to the Russian, often incomprehensible, weights, measures, and coinage; these are often accompanied with a request to make the contents known. If it proves impossible to prepare catalogues in Russian—though several British firms do so now—catalogues in German are well understood."

The difference in the class of machinery required in Russia, as compared with that used in the United Kingdom, should be borne in mind. The small and weak pony in Russia cannot draw a heavy plough. The Russian and Siberian requirements in many ways resemble those of Canada. Taking into consideration the peasant's general ignorance of machinery, and the fact that in all probabilty the nearest place where repairs could be effected would be at a considerable distance, Mr. Consul Grove makes the following suggestions—(1) Simplicity of construction; (2) lightness; (3) depôts where all sorts of machinery can be shown, and their construction, &c., explained in the local dialect to would-be purchasers; (4) interchangeable parts and standardisation of machinery; (5) accuracy of manufacture; (6) simplicity of arrangement; (7) cheapness and easy terms of payment; (8) careful packing.

The employment of electricity is rapidly increasing in Russia, and Germany still has the lion's share of the market. The installation of electric lighting in towns, and the conversion of tramways systems to electric traction, &c., is taking place in various towns,

and everywhere it is being done by Germans. The number of motor cars and bicycles is steadily increasing and seems likely to continue to do so, but Mr. Grove says that the only makers he has seen are French, a few Germans, and one or two so-called Russians, but no British. Typewriters again are now largely used and are to be seen in most offices in Moscow, but the import from the United Kingdom is quite nominal. Mr. Grove has "never been able to hear of a single machine of British manufacfacture." Ceylon and Indian teas used to be in considerable demand but there was a great shrinkage in 1903 and 1904. The war naturally interfered with the import *viâ* the Siberian railway, and so tea had mainly to enter by the European ports which may account for the smaller quantity imported, but the drop is remarkable. In 1901 the tea imported by Russia *viâ* the United Kingdom was valued at 7,250,000 roubles, in 1904 at only 3,330,000. There are many difficulties in the way of trade between the United Kingdom and Russia, but it is not easy to avoid the conclusion that this trade would be much larger than it is if British traders were more alive to the possibilities of the markets, and showed greater readiness to meet them.

AUTOMOBILE REGULATIONS IN GERMANY.

Regulations governing the use of automobiles in Germany are made by the police, and are always subject to change by simple order. All rules are strictly enforced. On arrival in the country the owner of a machine must go to police headquarters, give his name, age, place of birth, &c., and make formal application for a police number. No action can be taken until after twenty-four hours have elapsed, when if no objection is taken, a sealed letter will be given to the applicant to be delivered to an official appointed by the police, in most cases an automobile manufacturer or agent, who will fix a time to present the machine for examination. After the examination, a sealed letter is given by the examiner to the owner to take to the police headquarters. If all regulations are complied with, and the examiner s decision is satisfactory, after twenty-four hours, a police number, a foot square and made of tin, with number, &c. painted on it, will be brought to the owner of the machine, with a charge of one shilling and sixpence. The sign must be fastened to the rear of the car, and a lamp must be so adjusted as to throw a light upon the number. The following are a few points in the police regulations that are specially noted by the examiner. The car must have two separate and hanging brakes, each brake must be capable of bringing the machine to a standstill, while at a ten mile pace, within twenty-six feet, and the machine must be capable of being turned in a street thirty-three feet wide; it must emit no smoke or smell; the exhaust must not be in evidence in the streets; it must make no unnecessary noise, and it must be a safe and properly constructed machine. The lamps must be of clear glass, and throw a light sixty-five feet in the darkest night. The steering gear, brakes, and horn, must be so placed that the driver will not mistake them in the dark. A plate, with name of the machine, where made, number of horse-power and weight, must be in a prominent position, and the machine must not appear in the streets or on the roads without a number. No one under the age of eighteen years is permitted to drive an automobile. Police printed licenses on heavy linen paper are given free of charge. and must always accompany the automobile for police inspection. The license is always subject to withdrawal. The Customs duty upon a machine as a whole, landed in Germany, is about 4s. 2d. for one hundred pounds weight; lamps and detachable fittings are subject to an addititional duty. The duty on four rubber tyres is approximately 8s. 4d. Customs duties can be paid, subject to return, when the machine leaves German soil within one year, and the Customs seal is not broken, or off the machine. The American Consul at Aix-la-Chapelle, says that an American machine was recently refused a license in his district because all the above regulations, which, as before observed, are strictly enforced, were not complied with.

GUM ARABIC FROM THE SUDAN.

The trade in gum arabic from the Sudan shows an enormous increase during the last few months, while the price is very low. During the insurrection in the Sudan and while its markets were closed, gum was unobtainable from that region, but in the wake of conquest it began to be shipped again in large quantities from Kordofan, and the high price that had been obtained soon dropped. There were exported from Egypt 21,790,000 pounds in 1902 and 18,939,747 pounds in 1903. All Sudanese products are under a particular disadvantage from the high freight charges in the Nile Valley. Gum is gathered in the forests of the Sudan and is brought to Omdurman, opposite Khartoum, and is there packed, weighed, and forwarded to Cairo or to one of the seaports. There are, at present, three grades of gum recognised by the Sudan government. The first is the "hashab genaine gedaref," the second is the "gezira," and the third the "talh." The first quality is soft and white in colour, and is valued in Europe at 10 or 12 per cent. more than the second grade, which is hard and reddish in colour. The gum of this second quality is packed in parcels of from 370 to 385 pounds and is shipped in double sacks. The first grade, which is bought chiefly by chemists and druggists is, however, packed in wooden cases of 100 pounds each. The trade in Egypt is chiefly in the hands of a few merchants of Cairo or Alexandra.

HOME INDUSTRIES.

Fruit Growers and Railway Companies.—The Chairman of the Great Eastern Railway, in his statement at the General Meeting, referred to the carriage of fruit, and complained that growers are "too fond of adhering to old methods." The Departmental Committee of the Board of Agriculture, to whose report reference was recently made in the *Journal*, found that "the shortcomings of the British growers in not giving sufficient attention to the subject of grading and packing," have much to do with their failure to compete successfully with the foreigner. But the shortcomings are not all with the growers, who have the following complaints against the railway companies:—(1) Exorbitant rates; (2) preferential rates against the home grower; (3) preferential rates to one place over another in Great Britain, unfair incidence of charges and classification; (4) unpunctual deliveries; (5) bad handling; (6) pilfering; (7) inadequate service in many places, and unsuitable vehicles provided, especially on goods trains; (8) delays and losses in connection with empties; (9) difficulty in getting the companies to pay claims for damage or loss. And many of these complaints are, in the opinion of the committee, well founded.

Boxes v. Baskets.—The introduction of boxes for the carriage of fruit instead of baskets is recommended by railway companies. Boxes enable the fruit to be delivered to the market in the same state in which it is delivered to the company, for no pressure can affect a box, and any number of boxes piled one upon another can be conveniently packed in goods waggons in a way that cannot be done in the case of baskets. It may be expected, therefore, that boxes will soon be generally substituted for baskets, but much more remains to be done before fruit is carried and delivered as promptly, cheaply, and carefully as it must be if the home fruit industry is to have fair play.

Pedigree Stock and the Meat Trade.—For many years past there has been a large demand in the Argentine Republic for British pedigree stock, and the cessation or diminution of the demand has been expected by those who have an imperfect appreciation of the possibilities and needs of the Republic. The steady improvement in the quality of the meat exported, and the rapid growth of the meat trade, testify to the wisdom of the generous purchases of pedigree stock by Argentine breeders, and it almost all comes from the United Kingdom. The importation in 1904 was about double that in 1903, and it may be interesting to give particulars of it. The cattle imported were 1,124 shorthorns, 20 Herefords, 26 polled Angus, 14 red polled, and 7 Jerseys; also 2 various. The sheep imported were 2,559 Lincolns, 92 Rambouillet, 145 Hampshires, 232 Shropshires, 19 Oxfords, 54 Romney Marsh, 80 Leicesters, and 83 various. The horses imported were 30 racehorses, 45 Clydesdales, 22 Percherons, 5 Normans, 42 hackneys, 9 shires, 13 Yorkshires, 1 Suffolk, 2 Shetland ponies, and 2 others. The importation as regards pigs were 431 Berkshires and 61 Yorkshires. By a new regulation the pedigree has to be produced when the stock is placed in quarantine on arrival at Buenos Ayres. All the cattle, sheep, and pigs were imported from the United Kingdom with the exception of the Rambouillet, and of some sheep, mostly Lincolns, from New Zealand and Australia, which are well adapted to the Argentine climate. The horses also came from the United Kingdom for the most part. This year the Republic has taken the lead in the supply of fresh meat to the United Kingdom, the United States falling to second place. The effect of the foreign meat trade on the price of live stock in Argentine is shown by the following figures:—In 1902 cross bred steers were worth from 44 dols. to 48 dols., and cows from 34 dols. to 36 dols.; in 1905 they are worth, the one from 75 dols. to 80 dols., the other from 65 dols. to 75 dols. In the earlier year Lincoln wethers were worth from 5 dols. to 5·80 dols., and ewes from 3·20 dols. to 4·50 dols.; in 1905 the respective prices were 9·50 dols. to 10·80 dols. and 9 dols. to 10 dols.

The Motor Car.—The rapidly increasing use of motor cars is affecting various home industries to an extent as yet only very inadequately appreciated. The motor can do pretty well everything on a farm at a great saving of cost; it is proving of great advantage to railway companies as a feeder; it is supplanting the horse for municipal purposes; horse-drawn barges on the canals will soon be things of the past; the Post Office authorities are using the motor more and more. In many other directions it is revolutionising industrial conditions. For example, first-class sea-side hotels are being prejudicially affected by it. Visitors who used to stay at these hotels, said the Chairman of the Great Eastern Company at the General Meeting of the Company, have taken to "merely running down for the day on their motors." On the other hand the motor should help many inland inns.

The Treatment of Foreign Ships.—The Select Committee on the statutory requirements of foreign ships have reported and, as was anticipated, recommend that regulations as to overloading, unseaworthiness and the like enforced upon British ships shall be extended to foreign ships in ports of the United Kingdom. A foreign ship overloaded with cargo taken at a British port may be detained, but there is no other penalty provided, and no requirement as to marking. The Committee suggest that the Government should endeavour to arrange for the adoption of uniform rules of loading by the Governments of the principal maritime countries, and that power be given to the Government to apply by Order in Council in ports of the United Kingdom, the British rules as to load-line to the

merchant ships of any country not complying with rules as to loading which are not substantially equivalent to those in force in the United Kingdom. The Committee also recommend that Section 459 of the Merchant Shipping Act, 1894, should in future be applied to foreign as well as British ships. A British ship unfit for sea by reason of the defective condition of the hull, equipments, or machinery may be detained, and it is proposed to treat foreign ships in ports of the United Kingdom similarly.

The Watch Trade.—Probably no home industry of the minor sort has in recent years suffered more from foreign competition than the watch trade. The demand for highly finished and costly watches is no longer considerable. There will always be a few buyers of these watches, persons of means, to whom cost is not a primary consideration, and a few others ready to make some sacrifice in the purchase of an instrument they hope to keep as a life-long companion. But the general demand is for cheap watches, and largely for very cheap ones. Here the home maker cannot compete with his foreign rival, more especially the Swiss and American. The latter disposes of his surplus stock in this country at a price little or nothing above cost. By keeping his machinery fully employed he produces at a minimum cost, and he gets rid of, say, 80 per cent. of his output in his own country at a price that leaves him a good profit. The odd 20 per cent. it pays him indirectly to sell here at a price which may be said, roughly, to be 10 per cent. lower than the British maker can turn out the same article. Much of the watch trade done by Americans in the United Kingdom is in "movements," and the price accepted is so low that it has led to an ingenious device for checkmating American enterprise in this particular direction. American "movements" have been bought up in large numbers, and sent back to America for re-sale. As there is no duty upon the re-importation of American manufactures, and the cost of the transport of these particular goods is insignificant, a substantial profit has been made on the re-sales. So serious has been the effect that American watch firms located in this country now require a guarantee from wholesale buyers that they will not re-sell to persons intending to send back the "improvements" to America. The largest watchmakers in the United Kingdom are the Lancashire Watch Company, Limited, with headquarters at Prescot. The Company was formed by the late Lord Derby and other Lancashire gentlemen to manufacture complete watches on a large scale where all branches could be centralised, and machinery employed to the fullest extent. It does not cater for the very cheap trade.

The Letchworth Exhibition.—The cheap cottage exhibition at Letchworth is now open, and will be for the rest of the month. Its promoters claim that it demonstrates that cottages adequate to the wants of a labourer's family of the normal character can, under ordinary rural conditions, be erected for £150. And, taken literally, this statement is correct. The actual cost of materials and construction is not more than £150. But it has to be remembered that this sum does not include any fee for design; the building material must be obtained cheaply near the site; there must be no restrictive by-laws. Nor does the £150 cover any profit for the builder, or the cost of the land. What the exhibition shows is that a landowner anxious to house his villagers properly, well placed for materials and labour, and free of restrictive bye-laws, can put up good cottages for £150, which will enable him to allow villagers to rent them at a price within their means, and sufficient to return 4 per cent. upon the capital invested. (See *ante*, p. 939).

Carpet Designing.—British carpet manufacturers have their own causes of complaint in the matter of foreign competition. One of them relates to designs. Many of the large firms have a designing department, costing perhaps £2,000 or £3,000 a year, whose business it is to design new patterns for carpets. As soon as these patterns are delivered German agents go round to the retail shops and buy a yard or two of the new pattern to imitate and copy it on cheaper material. In this way they are able to sell what looks to the uneducated eye a pattern carpet similar to the one from which it is imitated at a price much below the cost of the English article. The German is within his legal right, and, provided he exercises a certain prudence in imitation, it is not easy to see how British firms can be protected from this particular form of unfair competition. It is not, of course, suggested that carpet designing in Germany is not common, or that in comparatively recent years there has not been considerable improvement in the manufacture of German carpets.

Electrical Supply.—As having some bearing upon the battle still raging between the existing electrical companies and the Administrative County of London and District Power Company, it may be noted that the Borough Council of Stepney, which has the most economical electrical undertaking in London, has entered into an agreement with the company for the purchase of a bulk supply, as have the local authorities of Bexley and Barking, while the Corporation of Croydon, which is the largest and one of the most successful electrical undertakings in the south of England, is supporting the Bill promoted by the company.

CORRESPONDENCE.

COAL IN INDIA.

I have just received (at Kargil in Baltistan) the Society of Arts *Journal*, dated 9th June, 1905. It contains a very short note, "Coal in India," which is a bundle of mistakes from beginning to end, and is

written by one altogether ignorant of Indian geography.

1. Coal has not been found in the vicinity of Srinagar. The coal-field referred to in the Geological Survey of India for 1904 is in the Jammu State.

2. The "course" of the railway will not depend upon "the position of the coal in the Jammu hills."

3. The coal has no "tendency to coke," whatever the writer may mean by the expression.

4. The coal seams near Namma may contain a considerable proportion of moisture, most coal does, but that would not make their value small. From the context one might suppose Namma had something to do with Jammu or Srinagar, instead of being the name of an affluent of the Myetrye (Namtu) that falls into that river near the capital of Hsipaw, one of the Northern Shan States.

I am led to writing the foregoing from the general accuracy which characterises the extracts in your *Journal* that refer to Indian affairs. I have not seen the geological report for 1904 yet.

C. M. P. Wright, M.I.M.M.

Srinagar, Kashmir.
July 5th, 1905.

[The note in question was based upon an article in a Calcutta weekly paper, before the Report of the Geological Survey of India had been received in England. The last paragraph, referring to coal seams near Namma, was not intended to indicate any connection with Jammu or Srinagar, but was added as coming under the heading of the article, "Coal in India.".—Ed.]

BRITISH TRADE WITH ROUMANIA.

Referring to the remarks made in the last issue of the *Journal* regarding the possibilities of extending British trade in Roumania (see *ante* p. 938), I should like to add that during my last visit to that country, I noticed a growing desire on the part of several Roumanian firms to increase their commercial relations with this country, but they complained of the indifference of British manufacturers or merchants to conform to the prevailing trading customs, and that they do not send enough travellers, or care to appoint local agents to push their goods.

In view of the improved legislation regarding the exploitation of forests, mines, and with particular reference to the development of the petroleum oil fields, and the encouragement given by the Government for the establishment of industrial concerns, the erection of light railways for private use, &c., there ought to be an inducement for *bonâ fide* investors and contractors to visit that country and investigate matters for themselves on the spot, and keep aside the unscrupulous speculators, of which there are a large number to be found. It must be pointed out that a great many of the past failures of doing good business in Roumania are traceable to such bad connections on both sides, and to the lack of the characteristic soundness of English business principles, and insufficient knowledge of the requirements of the people and country.

In a recent conversation which I had with His Excellency the Roumanian Minister here, I ventured to suggest that it would be advisable to have translated into English the new laws bearing on the subject of exploitation of mines, forests, erection of railways, &c., and to have the same widely circulated among interested parties. The Roumanians have learned to know that only with plenty of capital and with good organisation can success be attained.

L. Gaster.

32, Victoria-street, Westminster, London, S.W.
1st August, 1905.

GENERAL NOTES.

The Suez Canal.—Some interesting particulars are given as to the growth and present dimensions of the Suez Canal, by Mr. Consul Cameron, in his report on the trade and commerce of Port Said (No. 3448, Annual Series) just published. The navigable dimensions of the canal in 1905 are practically double what they were twenty years ago, the superficies of the vertical profile having been increased from about 320 to 580 square metres in the ordinary channel, and to 740 square metres in the numerous gares, or crossing places, the dredging being so carried out as to exceed the limits originally agreed upon. The following details are taken from a memorandum furnished by M. Perrier, the chief engineer of the company, to Mr. Consul Cameron. From 1869 to 1875 the canal retained its depth of 26 feet 3 inches, and its bottom width of 72 feet throughout its length of 99 miles. The crossing places were about 10 kilometres apart, each being about 1,100 yards long. From 1875 to 1884 the first improvements were made in straightening and widening the curves. During 1887 and 1888 the canal was widened half a metre, the bottom width being reduced (on the same slopes) to 18 metres. This extra depth allowed the transit of vessels with a draught up to 25 feet 7 inches. From 1888 to 1895 the bottom width was increased to 108 feet, and the curves were also improved. The result was the diminution in time of transit which had already been shortened by the use of the electric light since 1887, and ships could now pass at any point of the straight reaches of the canal, instead of only at the crossing places. From 1898 to 1904, owing to the increased dimensions of ships, larger passing stations were commenced, some twenty in number, at intervals of 3 miles, each passing station having an effective length of 820 yards with approaches of 328 yards at either end. At each the bottom width of the canal is 50 yards, the width at the water level over 100 yards, while the depth of the passing station itself is 9½ metres. At the same

time the depth of 8½ metres in the channel had been increased to 29½ feet, so that on January 1, 1902, a draught of 26 feet 3 inches was allowed instead of 25 feet 7 inches. The work of deepening the channel is steadily proceeding with the intention of arriving at a uniform depth of 31 feet. From kilometre 61, near El-Ferdan, as far as Suez, the bottom width is to be increased from 102 to 128 feet. The curves are also being improved, and a large crossing-place is being constructed in the small Bitter Lake. Taking the canal as a whole, it may be said that its width on the water level in the northern half is from 100 to 120 yards, and in the southern half from 80 to 100 yards. Lastly, the widening of the channel at Port Tewfik will enable battleships and large cruisers to coal rapidly alongside the buoys, instead of having to coal slowly in the roads.

THE PORT OF GENOA.—The work of enlarging the port of Genoa is to be begun this year. The cost of the enlargement is estimated at £2,000,000. The work is one of the very greatest importance to Genoa, and, indeed, to Italy in general, especially now that the Simplon Tunnel is completed. Exportation up to the present has taken little part in the traffic of Genoa, but it is hoped that it will become more important, and efforts are to be made to make Genoa a great centre for international merchandise, thus insuring vessels the possibility of finding return cargoes and merchants the power of sending their goods to all parts of the world. It is recognised that the Simplon Tunnel and other projected lines of railway between Switzerland and France will draw much traffic to Marseilles, and that the competition of the northern ports of Germany, the Netherlands, and Belgium will always remain very quiet. But if all the contemplated improvements in the port and the railway are carried out, says Mr. Consul-General Keene in his report on the trade of Genoa (No. 3446, Annual Series)—and it is essential for the vitality of the port that every facility should be given by the Italian railway authorities—encouragement would be given to merchandise being brought to Genoa from other countries for shipment to any part of the world. Supposing these hopes are reached, it is calculated that in twenty years the port of Genoa might attain a movement of 10,000,000 tons, which is nearly double the present annual movement, but this would necessitate a corresponding movement on the railways of 2,000 goods wagons per day instead of the 1,200 as at present.

BRITISH TRADE AND DELAGOA BAY.—Figures given by Major Baldwin, in his report on the trade of Lourenço Marques for 1904, show how much British trade with that port is suffering from the monopoly of the German East Africa line of steamers in the carrying trade between the competing European ports and those of the East Coast of Africa. The steamers of the Austrian Lloyd Company provide a monthly service, by the East Coast, between Trieste and Durban, and the British India Company's steamers have also a monthly service along the same coast, either to Bombay or in connection, by transhipment, with their European service from India, but for all practical purposes the German line has a monopoly of the direct trade with the great manufacturing and distributing centres of the continent. The effect upon shipping and the carrying trade is very marked. Whilst the total British tonnage entering the port decreased from 876,130, in 1903, to 854,027 in 1904, German tonnage in the same year increased from 216,194 to 267,832. Taking a wider view, it will be found that whilst in 1898 a total of 305 British ships entered the harbour, and only 50 German, in 1904 the British entries had decreased to 269 and the German increased to 71. No doubt it is the heavy subsidy which gives the German line the monopoly, but this monopoly is a great aid to German trade. "The existence of a direct, regular, and efficient line of national steamers," observes the Consul-General, "even although freight be neglected in agreement with other and indirectly competing lines, must tend to throw trade into the hands of the manufacturers of the country to which the line belongs, and those ports it is its principal business to serve."

DAMASCUS.—Electric lighting and tramway schemes seem incongruous when associated with Damascus notwithstanding its population of 230,000 or more, but according to Mr. Consul Richards (No. 3437, Annual Series), whose report is dated as late as June 1st last, a scheme of the kind is now under serious consideration with a view to its realisation. The possibilities of the enterprise have been studied on the spot by a competent Belgian engineer, who has sent in his report to Constantinople, and it is said to be distinctly favourable. Another public works scheme which has been under consideration during the past year, and is thought to be feasible, is a project for supplying Damascus with a good and abundant supply of drinking water from the Ain Fiji source of the Baroda River.

REGISTRATION OF TRADE-MARKS.—In his report on the finances and trade of the Argentine Republic (No. 3434, Annual Series), Mr. Harford, First Secretary to His Majesty's Legation at Buenos Ayres, points out that it is very important for foreign trade-marks on important articles to be promptly registered in the Argentine Republic, as cases have occurred where the trade-mark of a well-known firm has been adopted and registered by an unscrupulous person, and the real owner prosecuted for using it. The latter may even be cast in damages. The use of a showy and distinctive mark, combined with lavish advertising, will, says Mr. Harford, do more than quality alone to ensure a large sale in the Republic. It is also important to note that a contract signed in the United Kingdom cannot be enforced in Argentine unless it has been visé at an Argentine Consulate in the United Kingdom.

Journal of the Society of Arts.

No. 2,751. VOL. LIII.

FRIDAY, AUGUST 11, 1905.

NOTICES.

EXAMINATIONS.

The following is the Time Table for 1906:—

	Monday, April 2. (7—10 p.m.)	Tuesday, April 3. (7—10 p.m.)	Wednesday, April 4. (7—10 p.m.)	Thursday, April 5. (7—10 p.m.)	Friday, April 6. (7—10 p.m.)
Advanced Stage.	Book-keeping. English. Economics. Danish and Norwegian.	Arithmetic. Commercial Law. German. Italian. Spanish.	French. Commercial History and Geography. Typewriting (7.30 to 10 p.m.).	Accounting and Banking. Shorthand (150 and 120 words per minute), (7.15 to 10 p.m.)	Portuguese. Précis-writing. Russian. Swedish. Chinese. Japanese. Hindustani.
Intermediate Stage.	Typewriting (7.30 to 10 p.m.). French. Danish and Norwegian. Commercial History and Geography.	Book-keeping. Précis-writing.	English. Economics. Spanish.	Arithmetic. German. Portuguese. Italian. Russian. Chinese. Japanese. Hindustani.	Swedish. Shorthand (100 and 80 words per minute), (7.15 to 10 p.m.).
Elementary Stage.	Handwriting and Correspondence. French.	German. Italian. Typewriting (7.30 to 10 p.m.).	Book-keeping Spanish.	Shorthand (50 words per minute), (7.15 to 10 p.m.).	Commercial Geography. Arithmetic.
Music.		Harmony.	Rudiments of Music (7 to 9 p.m.).		

The last day for receiving entries is February 28th.

The special subject for Commercial History and Geography is:—Eastern Asia, including the whole of the Chinese Empire.

SECTIONAL COMMITTEES.

COLONIAL SECTION COMMITTEE.

The following is the list of the Colonial Section Committee, as appointed by the Council:—

Sir Owen Roberts, M.A, D.C.L., F.S.A. (Chairman of the Council).
Sir Westby B. Perceval, K.C.M.G. (Chairman of the Committee).
Earl of Aberdeen, G.C.M.G.
Hon. Sir William Arbuckle, Agent-General for Natal.
Lord Belhaven and Stenton.
Sir James Blyth, Bart.
Lord Brassey, K.C.B.
Byron Brenan, C.M.G.
Sir Thomas Fowell Buxton, Bart., G.C.M.G.
Hon. Sir John A. Cockburn, K.C.M.G.
T. A. Coghlan, I.S.O., F.S.S., Agent-General for New South Wales.
H. Bertram Cox, C.B.
Edward Dent.
Rt. Hon. Sir Charles Wentworth Dilke, Bart., M.P.
Hon. Alfred Dobson, Agent-General for Tasmania.
Hon. Sir Charles W. Fremantle, K.C.B.
Hon. Sir Thomas E. Fuller, K.C.M.G.

CANTOR LECTURES.

SOME ASPECTS OF ANCIENT AND MODERN EMBROIDERY.

By Alan S. Cole, C.B.

Lecture I.—Delivered May 1st, 1905.

The origin of our word embroidery is relatively modern, although the art of embroidery is of great antiquity. There seems to be no one corresponding word in Latin or Greek which is so comprehensive in possible meaning as that of our word embroidery. According to various authorities, it is derived from the French word "broder," which in its turn throws back to some Celtic source, such as the Breton word "brouda," to pierce, the Welsh word "brodio," to embroider, and the Gaelic "brod," a goad. Although we can use our word embroider in different senses, when we use it to indicate ornamentation done with threads as an enrichment to some textile or flexible material, we have of course in our mind work of stitchery done with a needle. But I hope to show you that embroidery may be equally well descriptive of thread ornamentation done in a manner less like that of needlework than that of shuttle weaving. In this case, the thread ornamentation plays a part in the actual construction of a textile. In the course of my two lectures on "Aspects of Ancient and Modern Embroidery"—and you will therefore understand that I am not attempting to give a comprehensive historical sketch of embroidery—I shall, amongst other matters, try and make clear by illustrations the characteristic feature (1) of embroidery as a method to construct or to complete the texture of a material partly woven in a loom, and (2) of embroidery as the needle-stitched embellishment of an otherwise complete woven material. In the one case, I think you will see that the embroidery is a necessary part of the woven material decorated with it, whilst in the other it is an addition, and therefore not essential to the construction of the material upon which it appears. Both, however, have a characteristic in common, which justifies each being called embroidery in a popular sense, as each is an expression in threads of ornamental intention. Moreover, each involves the use of an implement, which, however different as occasion required, was called by the Romans, at least, by the same name of acus.

Acus was a generic name, in fact, for a pointed implement. It meant equally such various things as the tongue of a buckle, a hairpin, a bone or wooden pointed instrument, large and small, as well as a needle with or without an eye to it, and, as compared with modern steel needles, a good deal bigger and coarser. In one shape the acus resembled a primitive shuttle or bobbin, in another a skewer. At one time we read of it as a needle, indispensable to the sarcinatrix, or mender of clothes; at another it is the pin with which the ornatrix, or slave who looked after the hairdressing and adornment of her mistress, fastened the loops and plaits of her hair together and fixed sundry ornaments to her costume. In another shape the acus was the particular instrument of the plumarius, who was a worker of ornament in coloured threads, and, so far as I can judge, usually adopted a sort of weaving or darning method for his work. Needle-stitched embroidery may have been done by another set of workpeople. It is, however, to these two distinctly different methods of ornamental thread work that I wish to direct some attention: and we shall see how at one period the two methods seem to have been concurrent in practice and how at other times one or other seems to have been the more ordinary method of embroidery. In whichever of its shapes we regard the instrument required for each method, whether

as a species of weaving or darning needle or as one particularly adapted for stitching, it is in both aspects the stiff-pointed continuation of the flexible thread in use. Unfettered by such contrivances as determine the possible movements of a machine, the needle in embroidery moves according to the taste and ingenuity of the fingers guiding it, and sweeps with perfect freedom along the surface or through the thickness of the stuff. Like pen or pencil it can be made to trace forms of any complexity, and, in two words, it writes and it draws. Used with a variety of coloured threads, its function resembles that of a brush in depicting tones and shades. The Romans frequently spoke of painting with a needle—"acu pingere"—and the craftsman who did such work was called "pictor," or painter.

In those days little, if any, distinction was made between the painter with a brush and the painter with a needle. Each seems to have had an equal standing with the other. Both usually were members of the body of slaves employed by a wealthy family, and we read that the members of such bodies were architects, builders, plasterers, statuaries, sculptors in low relief, decorative wall painters, weavers, embroiderers, gardeners, and the like. In the earlier times of the Roman emperors, the larger number of these slave artists and artificers attached to households were Greeks, whose ancestors for generations previously were, as we know so well, pre-eminently dexterous in all branches of art. Thus, as between Rome and Greece, we have an obvious continuity in the practice of such an art as embroidery, and of this we have several valuable and substantial pieces of evidence, to some of which I shall refer shortly. From Roman times down to the present, proofs of corresponding continuity are more plentiful.

In a previous course of lectures which I gave here ten years ago, I suggested various methods by which embroideries were wrought by Egyptians, Assyrians, Babylonians, and other more or less neighbouring Oriental people who were in frequent intercourse with one another during the two or three thousand years immediately B.C. I do not again review these methods, nor do I propose to touch on that extensive field covered by the embroidery of the Japanese, Chinese, Persians and Indians. In regard, however, to ancient Egyptian embroidery, a discovery made quite lately seems to have a very special interest for us in proving the prolonged use of that one method of embroidery which I have mentioned as a weaving or darning method. We can trace its employment in Greece and in Rome. When one finds at one end of a period the employment of a method which is in full practice at the other end of the period, it is, I think, fair to assume that such a method has had a continuous life during the whole period. Without having the material evidence which has now been obtained, I suggested in my lectures on "Egyptian Tapestry Weaving," in 1889, that this weaving or darning embroidery must have been in use at least 600 years B.C. I am therefore glad to find that my suggestion has been more than verified by the recently discovered fragment of the embroidered dress found with a mummy bearing the name of Amenothes the Second, whose date is about 1450 years B.C., or some hundred years before the Exodus. (Fig. 1.)

FIG. 1.

EGYPTIAN WORK OF AMENOTHES II.

Here, now, is this very interesting example, reproduced from the *fac-simile* published of it in an issue, dated 1904, of the "Catalogue Génerale des Antiquités Egyptiennes," by Messrs. Howard Carter and Percy Newberry. It is of linen and wool; the different emblems and devices are of coloured wools, which, being darned in between and over the unwoven linen warp threads, complete the whole texture of the piece. The ornament of the border is composed of alternating

flowers and buds, a version of the very ancient flower and knop pattern. Amongst the symbols we see that of royalty, consisting of two asps, one bearing the head-dress or crown of Upper Egypt and the other that of Lower Egypt—and their two up-turned tails merge into one another over the disc or solar emblem. The illustration does not show with distinctness the threads of the weaving and those of the embroidery, but in a bit of corresponding make, the characteristic of the method — in expressing ornament, at the same time making a fabric—is easily seen on a larger scale. The tapestry wall hangings of the fourteenth century and onwards were made in this manner; and later in my lectures as instances of a revival of the method, I shall show an illustration of one or two small articles, such as pouches, which were made last year in this country. This method, however, which we find to have been common in use for centuries, is not much mentioned in the various books on embroidery as holding an important place in the history of embroidery: it is indeed usually ignored altogether. As a means of embroidering costume and domestic cloths, &c., it is undoubtedly much slower and involves more labour than needle-stitched work. Its practice was compatible with the comparatively less rapid conditions of ancient times, and it is not surprising to find that, with the more extended activities of later times, it died out. Needle-stitched embroidery developed and proved itself to be of readier use and in some respects more telling in its effect than the darning embroidery.

With the Greeks of say the fourth century B.C. this darning embroidery seems to have been as usual a method for ornamenting woven stuffs as the needle-stitched embroidery. It appears to have been an occupation chiefly for women, and I have not come across a mention of Greek men embroiderers, none at least corresponding to that of Roman men embroiderers. In Greece, as for instance at Athens, embroidery was made almost solely for the very wealthy. It was done in their houses, where rooms were reserved for the women, who rarely went outside, living as enclosed a life as that of the cloistered nun of later times. The chief occupation of the Greek women, besides housework and preparing meals, consisted of spinning, weaving, and embroidery. Their work-rooms, without wooden floors or glass windows, gave on to inner courtyards, and, as compared with the ordinary modern English work-room, were no doubt somewhat draughty, and not too well lighted. Still it was in such quarters that the Grecian women lived their lives, and pursued their occupations. As a class, they were treated more or less as children in seclusion, their mothers and nurses were their teachers, and, beyond receiving a smattering of general education, the girls were trained in domestic work only. Time was of little account, so that a slow and regular acquirement of skill led to excellent work in such materials, linen and worsted, as were then available for it. From the indications we have, the patterns from which the weaving and embroidery were done must have been well drawn, and often of an intricate character. In some districts families or groups of women were bound by law to make festival garments for holy images. For instance, every four years upon the recurrence of the Panathenaic festival, a selection of Attic maidens wove and embroidered, for the figure of Athenæ, a peplos ornamented with portraits of celebrated men. Elsewhere, sixteen matrons were required to produce a peplos for the statue of Hera, at Olympia; and again, noble maidens of Argos discharged a similar task for a statue of Artemis, whilst those of Sparta worked a robe for Apollo. Thus, embroidery was not merely a home industry or occupation followed by individuals in respect of their own wants, but an art craft necessary for purposes of public ceremonial.

Of the very few illustrations on Greek vases, &c., of women actually engaged in some sort of embroidery, I have chosen one, which I now throw on to the screen. (Fig. 2.) The seated woman, as we see, is completing work in a small hand-frame. The kind of work is, I think, that of the darning and weaving to which I have referred; here, however, it appears to be in course of making, quite independently of linen. A larger frame would be necessary for linen cloths which were to be ornamented and completed with darning embroidery. A remnant or two of such Grecian work is preserved in the Hermitage, at St. Petersburg, and these I now show. The first displays a border of lotus-like blossoms darned or woven in coloured worsteds in between parts of an ordinary shuttle-woven material.

The next specimen worked in the same method is powdered with ducks. These specimens date from about the fourth century B.C., and so, too, does that shown in the next slide. The work here is of needle-stitched chain-stitch

embroidery of fair yellow-linen thread upon a reddish woollen material. The ornament of this latter piece is a good deal more elaborate than that of the two previous pieces. It is rather difficult to decipher it from the fragments; I have, therefore, made a drawing which I think correctly represents the pattern from which our Grecian embroideress would have worked her cloth or peplos. From these examples, and bearing in mind that the number of dyes was very limited, and that

FIG. 2.

GREEK WOMAN AT WORK.

silks with all their shimmering effects were not obtainable, we may conclude that Grecian embroideries before Christ were, as a rule, rather sombre in tone in comparison with the many-coloured silken embroidery intermixed with gold and silver threads of, say, 1,500 years later. Distinctly Greek in style, with its repeated anthemions, or honeysuckle devices, is this next specimen. It is of darning embroidery, and is the border—or paragauda, as the Romans termed it—to the neck of a tunic. The circumstances under which it was discovered point to its being probably seven or eight centuries later than the previous Grecian embroideries. It is, in fact, Grecian work of a rather late Roman period—say, about the third or fourth century A.D.

Now as regards embroidery in Rome during a period before the Christian era, we find that its condition as a home occupation or industry for women corresponded closely with its condition in Athens. It was followed in the quarters set apart for women in the houses of the richer class. These rooms, called in Greece gunaikonites, were gynecea in Rome: but the gynecea of the Romans were less closely supervised by their Roman mistresses and did not preserve, for so long a period as the Greeks did, their domestic, as distinct from a trade, character. As luxury increased the quarters allotted slaves in a Roman town or country house seems to have become converted into workshops suitably equipped and organised as trade workshops. The exterior rooms about Roman town mansions consisted frequently of shops and trade workrooms, tabernæ as they were called, whilst the owner of the mansion probably had, in the earlier times at least, a first call upon the services of the various artificers employed in the premises surrounding his mansion; later on these artificers and their workrooms served the public. Such development of Roman shops and trade workrooms seems to have been accompanied by the formation of workmen's societies, associations or, as they were called, collegia opificum. Amongst such associations were those of weavers and embroiderers. Their workshops were known as textrinæ, and in the first century A.D. there were several of them in the famous Vicus Tuscus which ran from the Via Sacra past the Basilica Julia. It was indeed a sort of Regent-street, noted not only for the textrinæ, but also for its perfume shops, and for the public processions which usually passed down it. The workshops of the weavers and embroiderers were generally one storey in height, and were evidently better than the underground dwellings of such craftsmen in Germany and parts of Northern Italy, of which Pliny took note, no doubt as being remarkably different from the work-rooms he was accustomed to see in Rome. The interior of a shop for the sale of textiles is given in a Pompeiian wall-painting preserved in Naples, and may quite well serve to represent a similar Roman shop, and to show that the conduct of business in a shop then was practically the same as it is now. I wish I could have found an illustration of weavers and embroiders at work. From descriptions, however, it is certain that the weavers or textores worked as a rule in company with a set of artificers called plumarii. Varro, writing in the first century A.D., particularly distinguishes the trade of the textores or weavers from that of the plumarii or embroiderers, and says that instruction in painting was a necessary part of their training.

The aspect which I have so cursorily given

of the textile craftsmen and women in Rome, corresponded doubtless with that of similar craftsmen in such Roman towns as Alexandria in Egypt and Antioch in Syria. From Alexandria and other Egyptian towns under Roman influence many ornamented textiles were imported by Rome, and a fashion for such things seems to have prevailed for many years, in support of which we now possess a large quantity of specimens taken from burying grounds in parts of Egypt. The greater number of them are embroideries done in the darning method to which I have already called your attention. Several of them are from designs distinctly Roman in style. Prior to the discovery, some twenty-five years ago, of these embroideries, a good deal of discussion took place as to the precise nature of work done by the plumarius. In his "Gallus," Becker comes to the conclusion that the plumarius did not adorn, with needlework, garments already made, but wove ornament in some special manner. As far as this conclusion goes it is sound, but it is now, I think, carried still further by the specimens which we possess of Roman or Egypto-Roman darning or woven embroidery, the technical method of which may be accepted as the special kind of work done by the plumarii. "Opus plumarium" is often mentioned in inventories of the thirteenth century, at which time the completion and adornment of stuffs with inwoven embroideries had been superseded by needle-stitched embroidery. The term "opus plumarium," as used in the thirteenth century, seems to be merely the survival of a term from classic times, and is not descriptive of long and short or feather-stitch needle embroidery. The Roman "opus plumarium" of the first few centuries A.D. seems to me to be exemplified by such specimens as I will now throw on the screen. You will notice that the method of work is the same as that we saw in the Egyptian cloth of Amenothes II., and in one or two examples of Greek work of the fourth century B.C.

Here is a square panel of this Egypto-Roman work (Fig. 3). The group of figures, somewhat rudely rendered, is evidently from a design of Roman origin. Venus is seated, Vulcan is raising his hammer, and Mars is about to draw or has just sheathed his sword. Panels of this description about eight or nine inches square were wrought on to the skirts of tunics.

Similar work was done on cloths, tablecloths, and cnshion covers, as in this slide. Here again the figures and animals are rather rude in rendering, but they are just such as may be seen, somewhat better drawn, in Pompeiian paintings.

Here is a tunic with large sleeves, ornamented with two broad bands of darning embroidery. This type of dress was in ordinary use in Rome during the first few centuries A.D. Many tunics were more elaborately decorated and with narrower bands. Here are a few specimens of such narrower bands, all of darning embroidery, which, with the woven linen about it, completes the fabric. The centre band with vases and baskets in alternation is distinctively Roman in style.

We have not much evidence of needle-

FIG. 3.

EGYPTO-ROMAN SQUARE.—VENUS, VULCAN, MARS.

stitched embroidery at this period, and little more I am afraid than a side light is thrown upon the employment of women in textile arts by such an illustration as the one now shown. It is taken from a painting in a MS. of the fifth century A.D., which is known as the Genesis fragment of the Imperial Library at Vienna. One lady with the child at her knee is spinning or winding thread, and the other one may perhaps be doing some sort of embroidery. At this date rich persons wore costumes plentifully ornamented, and the fashion was censured from the pulpit by Asterius, Bishop of Amasia in Pontus. "Every one," he said, "is eager to clothe himself, his wife and his children with stuffs ornamented with flowers and numberless figures, and to such an extent is this done, that when the wealthy classes show themselves in public, little children gather round them in crowds and point their fingers at them, making merry at their expense. The more religious of the wealthy classes

require artists to supply them with subjects taken from the New Testament." Some idea of this condition of ornate costume may be got from the well-known sixth century mosaic of the Empress Theodora and her ladies at Ravenna. I imagine that the greater quantity of the ornamentation here displayed was of darning embroidery, and little, if any, of needle-stitched embroidery.

The four specimens on this slide are of needle-stitched work, and that on the lower left corner is possibly of sixth or seventh century work from a design which is, for that time, of fairly good standard. It is wrought in silks of brilliant colours, crimson, green, yellow, &c., the forms of the figures and their draperies being outlined in black. The other three bits are obviously worked from poorly drawn designs; all of them, however, are of a Christian religious character. These embroideries were wrought originally on tunics, worn by Romans or Byzantines who died in Egypt, but they none the less serve to illustrate a style of embroidery which was equally familiar with Romans and Byzantines living in their own countries.

I am now about to try and deal, but only in a very general manner, with the conditions that arose and were favourable to a large movement that fostered the arts of designing, religious subjects particularly, and of embroidering them. Zeal in spreading Christian doctrine lies evidently at the root of such movement, which was very largely due in fact to monasteries, convents, abbeys, and the like. These came to be rapidly established throughout Italy, France, and Britain, which I specify because the examples of ninth, tenth, and eleventh century embroidery I have chosen as illustrations, were apparently made in the two last-named countries—France and Britain, whilst the first-named, Italy, is practically the birthplace of that form of the monastic movement of which I think we must take chief notice.

"It is," says Mr. I. W. Bradley, in his useful handbook upon illuminated manuscripts, "a curious and important synchronism that, whilst Justinian was reviving the splendour of Roman arms and political life in the East, St. Benedict was creating the great religious foundation of Monte Cassino, which was to become the preceptrix of the West in religious literature and art. Such was its fame within the lifetime of the founder that most of the existing communities were eager to adopt its rule; and by the eighth century a number of busy offshoots were, not merely continuing, but striving anxiously to increase and disseminate its practical teachings as the basis of the new Christian civilisation." The monastic life had come from Egypt into Italy about the fourth century A.D. It was a life chiefly of fasting, meditation, and prayer, but so frequently had it degenerated into one of idleness, listlessness, and even self-indulgence, that it called into action a reformer in the person of St. Benedict, who appeared on the scene in the sixth century to put matters right. He framed a code of rules by which a monk's time was to be devoted as much to work as to religious exercises. The leading occupations were to be worship, study, and labour. Benedict's code is voluminous and precise, and is probably the most famous of all monastic codes. Amongst its regulations there is one requiring abbots of monasteries to provide each monk with a knife, a pen, a needle, a handkerchief, and tablets, thus enforcing a general provision of those very things which, in the hands of able and enthusiastic monks, would inevitably, it would seem, lead to systematic practice in writing and drawing and needlework, equally for utilitarian or decorative purposes, or for both.

Illuminated manuscripts—some few with authentic details as to how, when, why, and by whom they were produced—have come down to us from the time of St. Benedict, and convince one that a widespread obedience to his rules was long sustained, and was attended with many results of fine writing and illumination. As regards embroidery, the evidence is not so direct; still, it seems to be sufficient for something more secure than plausible inference alone. It was a craft, and as such would come under another part of the Benedictine Code, which prescribed that craftsmen in various callings amongst the brethren were to undertake work with the abbot's permission. When their work was for sale, those brethren entrusted with making the bargains were to deal honestly with purchasers, and to sell rather below than above current prices. The nunnery established also at Monte Cassino by St. Scholastica, Benedict's sister, was carried on under corresponding regulations, and it is reasonable to suppose that, under the favourable conditions of their life, Benedictine nuns would, like other women of the times, have paid particular attention to cultivating the arts of embroidery, weaving, &c., taking for their designs those which neighbouring monks had as a rule the greater skill in making.

From an illuminated, or rather a well illustrated, codex respecting all sorts of things—a mediæval encyclopædia—written by a scholar of great distinction, Rabanus Maurus, in the ninth century, I have taken a page showing the crafts of spinning or winding threads and work of a weaving character pursued in the gynæcea, or women's work-rooms, of his time (Fig. 4). From the character of the frame, and the stretched rank of warp threads, it must be not an ordinary shuttle-weaving loom, but a darning or tapestry-weaving frame, alike, in its essentials, to the tapestry-weaving frames which are pictured with women working at them, in manuscripts of much later date.

FIG. 4.

GYNÆCEUM FROM THE CODEX OF RABANUS MAURUS.

Rabanus Maurus was elected abbot of Fulda in Germany in the ninth century, and compiled his codex, or encyclopædia, in his retirement. His codex is now preserved at Monte Cassino, and, as may be easily supposed, is an historical document of very great interest. It throws light upon the general condition of civilisation and industrial employments, the development of which was due at that time practically to the monasteries and their missionaries. That at Fulda, in the eighth century, was as notable for its high standard of activity as those at Monte Cassino, at Tours, and at York. Historians have told us how intimate the relations between such centres far distant from one another must have been. Some forty years before Rabanus Maurus was abbot at Fulda, Eginhard, the biographer of Charlemagne, had been educated there. His artistic skill was such that he received the name of Bezaleel, who, as we read in Exodus, was the architect and decorator of the Tabernacle or Sanctuary, a man filled with the spirit of God in wisdom, understanding, and all manner of cunning workmanship, including embroidery. Early in life, on account of his great abilities, scholastic and artistic, Eginhard was appointed to the household of Charlemagne, who contracted a close and lifelong friendship with him. Similarly, the Emperor, zealous to promote learning and practice of the arts, enrolled in the circle of his intimate associates and advisers Alcuin, the distinguished scholar and head of the then famous Church School at York. The Emperor had met him casually at Parma, and made his acquaintance, and quickly discovered its great worth. Incidents like these indicate the cosmopolitan and progressive character of the Emperor, and how zealous he was to guide and promote the general social developments of his kingdom.

The boundaries of Charlemagne's kingdom included all modern France and some part of modern Germany, and, scattered over these countries, as well as Britain, were several Benedictine monasteries and convents, working with more or less united enthusiasm for the spread of learning, religion, and the arts. Some naturally excelled in their artistic performances, whether in the direction of writing, illumination, or embroidery, or otherwise. It is easy to see, however, that such an extensive organisation became powerful in its religious and educative influences under the practical interest which Charlemagne manifested in it, and the many branches of its operations. With the help of friends such, amongst others, as Eginhard and Alcuin, he organised a large body of officials, experienced men, both of the laity and clergy, to travel about, inspect, report, and advise upon the various educational, artistic and other enterprises which were being carried out locally by the different bodies concerned with them. These officials were called missi dominici. The instructions issued to them were very detailed and precise, and their advice and inspection must have generally acted as a stimulus to the inmates of the abbeys, monasteries, and schools. It was the custom of many of these establishments to send presents to the Emperor, and inspectors were told to recollect "to order that they who send me horses as presents inscribes their names on each horse, and so with dresses that may be sent us from abbeys."

In connection with this mention of dresses I now refer to a sumptuously embroidered dalmatic, preserved at St. Peter's, in Rome. The tradition is that it was worn by Charlemagne on Christmas Day, 800, the date of his Coronation as Emperor of the Holy Roman Empire. He is then said to have sung the Gospel at High Mass, vested as a Deacon. Some have ascribed this very fine specimen of embroidery to the hands of the Emperor's wife; others have doubted it being work of the ninth century and have urged reasons for regarding it as work of the twelfth century. It seems to me to be far too elaborate in design and technical stitchery to have been done by an amateur embroideress, notwithstanding her exalted position as an Empress, a view also applicable, I think, to the idea that Matilda, wife of William the Conqueror, worked the Bayeux Tapestry. Both of these historically famous needle-stitched embroideries are more probably by embroideresses who were kept pretty closely to their work, doing it under guidance from designs specially drawn by such competent draughtsmen as lived at the respective periods concerned. Now this combination of skill at each period may be confidently looked for at abbeys and monasteries. I will here show two illustrations of the Charlemagne Dalmatic. It is of blue silk, embroidered with gold and silver threads mainly, though picked out here and there with red and black. The event depicted on this side of the vestment is apparently the Ascension. The central figure of Christ is worked in silver, and the figures below are in gold. The smaller figures on the shoulders and short sleeves represent the administration of the Communion. In the central and important composition, Christ is shown as a man with a beard, a type of portraiture more common according to Christian iconography after the tenth century than before it. The other side of the dalmatic gives us a more formal arrangement of figures, with one representing Christ as a youth beardless, seated and as a sovereign, surrounded by angels, and earthly magnates, grouped into a circular arrangement within a roundel. (Fig. 5). In this composition, the central figure of Christ is golden and the surrounding subordinate ones silver, thus reversing the order in which these metal threads were used for the back of the vestment, and indicating the designer's appreciation for the effect of a calculated counter-change of colour. Similarly, his appreciation of the value of contrast is shown in the free and open arrangement of figures on the back, and the circumscribed and closer arrangement of figures on the front. The obvious attention which has been given to æsthetic principles in producing the design, as well as to its epical or story-telling interest, point, as I have said, to the work having issued from some centre, equipped in all respects for constant practice of the decorative arts by competent hands. The beardless Christ, according to Christian iconography, is a more frequent type from the third to the

FIG. 5.

CHARLEMAGNE DALMATIC. (BEARDLESS CHRIST SEATED IN JUDGMENT.)

tenth century than later. The fact that both the bearded and beardless Christs appear in this one specimen suggests a compromise in date which goes in favour possibly of the work being of the ninth century, that is of the time of Charlemagne. The circular grouping of the subordinate figures around the central figure is remarkable. It is unusual, and, so far as I have been able to trace it, seems to have been a scheme of composition not often affected by certain of the monastic artists of the eighth century.

In an illuminated MS., a Sacramentary given by Charlemagne, about 826, to his natural son Drogo, Archbishop of Metz, we find an initial C, enclosing a circular grouping of figures

which represent the Ascension; Christ is the central predominating figure on the hill or mound, stretching his hand to that of the Almighty, which issues from the clouds. About and below the mound are the subordinate persons associated with the event. This MS. was probably written and illuminated at the celebrated abbey of St. Martin, at Tours, of which Alcuin, after rendering many years' service to Charlemagne, was appointed head early in the ninth century. This abbey of St. Martin's was one of the wealthiest in France, and some notion of its size and influence may be derived from the fact that there were more than 20,000 labourers or serfs employed on its domains, exclusive, of course, of the inmates of the monastery, in which the enrichment of the

FIG. 6.

CHARLES THE BALD, BIBLE ILLUMINATION.

library with MSS. engaged the special attention of Alcuin during the later years of his life. Under him the abbey rose to still greater fame as one of the best schools of writing and illumination.

Another splendidly illuminated MS. produced at Tours, and almost contemporary with the Sacramentary of Drogo, is a Bible presented by Vivianus, a successor to Alcuin in the abbacy of St. Martin, to Charles the Bald, who came to the throne of France in 840. From this Bible I have taken the celebrated full page illumination depicting its presentation to the king, who is the central figure, seated, with attendants near him on the right and left and the dignatories of the abbey below; all these subordinate figures are arranged into a circular group. (Fig. 6.) If this circular group of figures were put into a medallion and the architecture were omitted, we should still see more plainly how very similar the composition of it is to that of the medallion containing the beardless Christ on the Charlemagne Dalmatic.

Notwithstanding the views put forward in considerable detail by Monsieur Didron in his "Annales Archéologiques" in favour of this vestment being twelfth century Byzantine embroidery, I think, especially after seeing many of the daintily painted ornaments in other pages of the Vivian Bible and the Drogo Sacramentary, which are similar in style to many in the Dalmatic, that there are reasonable grounds to regard the Dalmatic as a fine specimen of work of the first half of the ninth century, which may, indeed, have been made at the abbey of St. Martin at Tours, but that it was worn by Charlemagne at his coronation in St. Peter's is less probable.

Its embroidery, showing great skill in stitching gold and silver threads so as to present a flattened surface, is remarkable and is typical also to some extent of a class of work that seems to have been much practised during a period from the ninth to the twelfth centuries, if one may judge from the few remains that have been preserved and are now available; the better of the embroideries, and possibly also the larger number of them, were made in England.

I now show an example of this class of fine English embroidery of the early tenth century which is preserved in the Chapter Library of Durham Cathedral. On the slide are three portions only of the stole, figured with Prophets and small conventional leafy ornament worked in fine coloured silks picked out with gold threads with which the background is wholly worked. The names of the Prophets in capital letters are worked close to the figures, of whom Hosea and Joel are in the centre piece: Isaiah on the left hand, and Daniel or Amos on the right. In a part of the stole not included on this slide, is an inscription in similar letters to the effect that it was made to the order of Aelfflaed, Queen of Edward the Elder, who reigned from 901 to 925, and was presented by her to Friedestan, who was Bishop of Winchester from 905 to 931. Winchester was the seat of Royalty in England, and its monastery became celebrated a few years later under the influence and direction of Dunstan, Archbishop of Canterbury. But even in the beginning of the tenth century Winchester was notable for its art in producing MSS. The Archbishop himself was a skilful artist, having acquired his skill when a monk at Fleury or Benoit sur Loire. The late Rev. James Raine, Librarian at Durham, suggests that the embroidery now before us was most probably made at Winchester. The design for it is a good example of the style of figure and ornamental designing that then prevailed at the best foreign, if not also English, monasteries. If the designs for these embroideries are not by English hands, it is not unlikely that some Frankish monks, illuminators, settled at Winchester, may have made the designs. However this may be, authorities on the subject seem to agree that the drawings of the Winchester school, after it came under Archbishop Dunstan, during the latter part of the tenth century and in the eleventh century, possess an English distinction which, especially in regard to fine freehand outline drawings, resulted from the grafting, as Sir Edward Maunde Thompson writes, of a foreign style upon that of the Anglo-Saxon draughtsmen, giving it strength and checking its peculiarities, freeing it to a large degree from what strikes us as grotesqueness, and fostering a realistic representation of incidents and human figures taking part in them. I venture to call attention thus particularly to the eleventh century Anglo-Saxon freehand drawing, as done in monasteries, on account of the interest attaching to a comparison between it and the drawing involved in such a needlework as the Bayeux Tapestry.

Many writers upon this historical needlework have not, I think, directed much attention to the value of such comparison as one of the means by which further light may be thrown

probably upon the origin and actual production of this unique embroidery. As a suggestion in this direction, I have taken two outline drawings from an MS. in the British Museum, known as Aelfric the Grammarian's Anglo-Saxon paraphrase of the Pentateuch, written and illustrated at the same time, namely, the eleventh century. These drawings are in the nature of illustrations and cannot be regarded as illuminations. In the first of them we have a scene of the two angels at table partaking of the hospitality of Lot who is entering the feast room; behind him follows a servant bearing a bowl. The attitudes of Lot and his servant and architectural features will be seen to be closely similar in style to many attitudes and architectural features in the Bayeux tapestry. Again, the second drawing (see Fig. 7),

FIG. 7.

OUTLINE DRAWING FROM ÆLFRIC'S PENTATEUCH.

which displays a large canopied hall and Lot speaking to his sons-in-law, is strikingly similar to corresponding figures and surroundings pictured in the Bayeux Tapestry. With the impression of these drawings fresh in our eyes, let us glance at a small part of the Bayeux tapestry, very fully described and discussed in Mr. Fowke's book on the subject.

Here we have King Edward the Confessor seated on a cushioned throne. With his right hand the King emphasises the remarks he addresses to two persons of rank standing before him. Of these one is undoubtedly Harold, who is taking leave of his master previous to quitting the court. Harold is wearing a moustache. And here we see him and his knights riding to Bosham. Harold and an attendant, having dismounted, enter the church: and are then entertained at some neighbouring house in a solar or upper hall, the place peculiarly set apart for eating and drinking.

The next incidents depicted are the sailing of Harold and his suite to the land of Count Guy, arriving on the coast of Ponthieu. Harold in full costume approaches the shore, the anchor of his boat is cast and he prepares to land. He is seized by the Count Guy, who conducts him to Beaurain and there imprisons him. Then follows a scene in which Count Guy, seated on a throne in a canopied hall, converses with his prisoner, Harold (Fig. 8). After this we have two knights who were sent by Duke William of Normandy to treat with Count Guy. And here the messengers returning to the Duke, who is seated, bearing in his left hand a sword.

Now all this needle-stitched embroidery naturally results in a heavier effect than that of the pen outline drawings of Aelfric's Pentateuch, but, notwithstanding this, I think that the gesture of the figures, the expression of their heads, their hands, legs, and feet suffice to show that the mannerisms of drawing in the one reappear nearly in the other. To this day the Bayeux needlework is officially called "la tapisserie de la Reine Mathilde." Of course it is not a real tapisserie or hanging woven in the well-known method, but is a needle-stitched embroidery. Moreover, as Mr. Fowke writes, there is nothing to connect the work with Mathilda. It was, he concludes, probably ordered by Bishop Odo to decorate his cathedral at Bayeaux, completed, however, forty-six years after the Norman Conquest. The length of the nave of the Cathedral coincides with the length of the embroidery. Whether Odo caused it to be designed and partly worked in England during the time when he was left by William the Conqueror in charge of Kent a few years after the Conquest, or whether it was done early in the twelfth century in Bayeux, are questions to which it seems impossible now to give conclusive answers. England was at the time becoming famous for her needle-stitched embroidery, and was noted for freehand outline drawing; it is possible that Normandy was equally so. The discovery of an original drawing for the Bayeux embroidery, signed and dated, would be an event of supreme archæological interest.

Very briefly let me recapitulate the main points touched on in this lecture. We have had evidence that the same character of darning or weaving embroidery was in practice from 1400 B.C. until the sixth or seventh century A.D.; that needle-stitched embroidery

was done from the fourth century B.C. up to the end of the eleventh century; that needle-stitched embroidery seemed to supersede the darning or weaving embroidery from about the eighth century A.D. onwards. We have seen indications of a connection more or less close between the art of MS. illumination and needle-stitched embroidery from the time of Charlemagne to the twelfth century, and we have had some slight suggestions of the domestic and other conditions under which embroiderers from the fourth century B.C. to the eleventh century A.D. have

FIG. 8.

BAYEUX NEEDLEWORK. (WILLIAM SEATED AND MESSENGERS.)

worked, and how at one period embroidery seems to have been used by wealthy Greeks only, and then more generally by Romans in the decoration of everyday costumes; and how in a succeeding period it seems to have been used almost exclusively for ecclesiastical vestments. The Bayeux Tapestry has shown us an exceptional use of embroidery as a means of recording upon a wall hanging a secular historic event. In my next lecture, I propose to treat chiefly of embroidery in England from the eleventh century onwards to the present day, and to give aspects of it corresponding with those few which have been dealt with in this evening's lecture.

THE HOUSING PROBLEM.

Not the least valuable portion of the Report of the Royal Commission appointed to inquire into and report upon the means of locomotion and transport in London, is that section of it which deals with the housing problem as affected by the facilities for locomotion. The over-crowding of the metropolitan area is, generally speaking, greatest in the central area, and tends to diminish towards the circumference. According to tables furnished by the statistical and other officers of the London County Council, the population per acre in the central area of London is 148, in the rest of the county excluding North Woolwich) 16·6, and in the rest of "Greater London" 2·5. Upwards of a million and a-half people live in the central, or most congested area, and the average weekly rents for workmen's dwellings are highest in the central and most crowded districts of London. In this area the average weekly rent of newly-erected, working-class houses is 3s. 3½d. per room, in the rest of the county 2s. 4½d., and in "Greater London" 2s. approximately. It is, in fact, impossible to re-house the working classes within the central districts, at rates which they can afford to pay without a heavy loss to those who undertake the re-housing. This is shown by the experience of the London County Council in connection with the formation of the new street from Holborn to the Strand, now in course of completion. Under the authorising Act, the Council was required to build workmen's dwellings in place of those that were demolished. For this purpose they bought the Bourne Estate, close to the site of the improvement. The cost price was £201,147, being the commercial value. They were obliged to write this sum down to £44,000, its value ear-marked for artisans' housing, and to debit the balance to the cost of street improvements. This was necessary to admit of charging rents within the means of the families to be provided for. And the families so provided for must be limited to those earning very substantial wages, seeing that the rents charged are from 9s. 6d. to 11s. per week for a three-roomed tenement, a rent that only the well-to-do artisan can pay. Even upon this rental there is a loss of nearly £60 per head of the persons re-housed. The buildings erected accommodate 2,640

persons, and the whole of this has fallen upon the rates.

The Royal Commission contrast this result with the outcome of the London County Council experiment at Tooting. They acquired land there at a price which required no writing down, and are now letting three-roomed cottages at from 7s. to 7s. 6d. per week, rentals which entail no loss. "The lesson to be learned from the two cases," says the report, "is confirmed by every housing scheme without exception that the London County Council has undertaken; whenever they have had to provide workmen's dwellings in central districts there has been a heavy loss. In effect the rents are largely paid out of the rates. In the few cases where they have provided dwellings outside the schemes have been self-supporting so far as the houses have been built." It may be mentioned that this is not the unanimous opinion of the Commission. In a separate report Sir Joseph Dimsdale denies that the housing schemes of the London County Council for providing workmen's dwellings outside the central districts of London have been self-supporting so far as houses have been built, and that in those cases there has been no loss of money at all. "Perhaps," says the City Chamberlain, "the largest of these is that of the Council's housing scheme at White Hart-lane, Tottenham, for accommodating 42,500 persons at an estimated cost of £1,972,602. It will not, I think, be denied that the rents, varying from 6s. 6d. to 9s. 9d. per week, for the Council's five-roomed tenements at Tottenham do not include rates, which are paid by the tenant in addition to the before-named rents. As the rates, even on such tenements, are exceedingly high, a workman occupying one of them would appear to be a prosperous man if able to afford something like 10s. 6d. to 13s. 9d. per week for his house accommodation. A six-roomed tenement not belonging to the Council can be obtained at Tottenham for less money than a five-roomed tenement under the Council." Be that as it may, the evidence taken by the Royal Commission would seem to warrant the conclusion at which it has arrived, namely, that it is not practicable to re-house the working classes in the central districts at economic rents.

It used to be assumed that the persons displaced in consequence of an improvement or a clearance would occupy the new buildings. It was upon this assumption that past legislation was based. But experience has shown that this is not the case. The interval of about two years which occurs between demolition and reconstruction disperses the persons actually displaced. "Even," says the report, "in cases where the London County Council has carried out clearances in sections, and has thus been able to offer new accommodation before complete displacement took place, little or no advantage has been taken of the opportunity. For example, in the Boundary-street area, out of 5,719 persons displaced, only eleven returned to the new buildings." Under the Housing of the Working Classes Act of 1903, a discretion is now vested in the Local Government Board which enables them to authorise re-housing at a distance from the demolished buildings instead of in close proximity as formally, but without facilities for locomotion this discretion cannot be generally exercised. The Commission insist very strongly upon the importance of locomotion as affecting the working classes, nor is the importance of facilitating rapid and cheap locomotion a matter that concerns only the working classes. It naturally affects the health, comfort, and efficiency for work of the whole community. Where facilities for locomotion have been afforded, the population does, in fact, take advantage of them to live outside London. This is illustrated by the increase in the population of Edmonton and of Walthamstow since the Great Eastern Railway Company commenced to run workmen's trains to these places. These trains were started in 1871, and the population of Edmonton at that time was 13,860, and of Walthamstow 11,092. In 1883, the company began to run three trains instead of two, and in 1891, the population of the two places had increased respectively to 36,351 and 46,346. In 1899 the five trains were increased to seven, and in 1901 the population had increased to 60,892 and 95,131 respectively, an increase largely due to the more rapid and cheaper locomotion. Leyton affords another example, the population having more than doubled in ten years from the same cause. The difficulty is to provide those facilities of locomotion which can alone make it possible for the working classes to take advantage of lower rents outside London proper. The railway companies are not generally prepared to construct lines leading to districts which are sparsely occupied. The railway commissioners have held that Parliament did not intend by the Cheap Trains Act to throw upon railway companies the duty of opening out neighbourhoods for the creation of new workmen's residential districts, and that they have consequently no power to order the running of a service of workmen's trains unless and until it can be proved that a demand for such trains exists along the line. Accordingly many places otherwise suitable for building workmen's dwellings are not accessible by railway, and others that are accessible cannot be utilised for residence by the poorer people working in London owing to want of trains of sufficient cheapness and frequency. A consequence of this state of things is a great aggregation of the working classes in those districts which have been opened out, and the presence of so many houses of comparatively low rental has discouraged the construction of better-class houses. For example, in Walthamstow, out of 18,600 houses, 15,000 are assessed at less than £16 a year, which means a low rateable value and a rate in the pound high in proportion. It is insisted by the Royal Commission that if the housing problem is to be solved, or overcrowding in London relieved to any appreciable extent, means must be provided for taking the popu-

lation into and out of London, "not in one or two directions, but in many directions, at rapid speed, frequent intervals, and cheap rates."

RUBBER PLANTING INDUSTRY IN CEYLON.

Writing in his Annual Administration Report in Jannuary last, the Director of the Royal Botanic Gardens, after referring to the statistics in "Ferguson's Directory" for 1904-5, came to the conclusion that, at the beginning of this year, there were about 25,000 acres under rubber cultivation, including all the kinds planted in Ceylon, Para, Castilloa, Ceara, &c. Not many years ago, Dr. Willis hazarded the opinion that, perhaps, 10,000 acres formed about the limit of area in Ceylon of suitable land available for the Para (Hevea) variety. We all, at that time, supposed that the Kalutara district presented the type of soil and climate required. But the ideas of rubber planters and scientists have been greatly widened since, "with the process of the sun," and through the valuable additional experience obtained. No one is certain now of the exact limit, whether in altitude or climate, for the profitable cultivation of Para; and nothing can settle this, but the result of experiments now being made in districts so varying in their character, elevation, rainfall, soil and climate generally, as Monaragala, Passara, Lower Haputale, the uplands of Uva, Lower Dimbula, Ambagamuwa, Kadugannawa, the various division of Matale, Dumbara and Medamahanuwara, the country from Kurunegala right along by Kegalla to Ratnapura, including the Kelani Valley, the Kalutara and Galle districts, and possibly some of the districts North of Colombo with stretches along the Northern Railway, and the plantings of some years ago near Trincomalee. Facing all the facts and figures presented to us on the present occasion, we feel difficulty in attempting to treat of the probable development of our great rubber industry during the next few years? Who dare say "whereunto this would grow?"—to quote classical words of old. For, already, we have to deal with one of the most important developments of planting ever originated and carried on in Ceylon. And here we must say that the gratitude of the colony is due to the late Drs. Thwaites and Trimen, for the great interest they took in obtaining the first rubber plants from Kew for Ceylon, and for their special care of the same. It must be remembered that Ceylon got the plants from Para which belonged to, and were intended for India*, and that these growing at Henaratgoda into large trees, now some 28 years old, are the parents of most if not all in Ceylon, the Straits, Southern India and Burma. Although Dr. Trimen gave full information in successive reports, year by year from 1883, yet progress among planters was very slow—owing to the time required to develop the tree, doubts as to the result in latex, and the great success of the tea bush—so that by March, 1898, Ceylon had not more than 750 acres of rubber, and by May, 1901, this area had only doubled; while in summing up the situation early in 1902 we supposed there were from 2,600 to 3,000 acres. Then a great start took place and for the middle of 1903, our estimate sprang up to 12,000 acres, and, as already stated, Mr. Willis considered this had more than doubled by the end of 1904, and that the colony had by January last 25,000 acres under rubber. The continued marvellous activity of the past six months and the strenuous way in which clearings have been formed for limited companies or private proprietors, apart from the free planting of rubber among tea, is shown by the fact that we find an increase of nearly 44 per cent. in the area cultivated since January last. No doubt in some cases clearings are returned which are only in process of being planted during the current monsoon season; but allowance can be made for such in accepting thirty-nine thousand acres as representing the area covered by rubber in Ceylon in July, 1905. The way in which we arrive at this result may be judged from the following totals worked out of the estate returns:—

	Acres.
Area under rubber only	20,096
" " rubber and tea	5,282
" " rubber and cacao	3,316

Number of rubber trees separately returned, 2,589,377, and counting 175 of these as equivalent to an acre on an average, we get an equivalent of 14,796 acres; and taking half the extent where rubber is returned above with tea and cacao, we get the grand total of 39,140 acres as representing the rubber industry of Ceylon at this time. With this we may contrast the latest figures for other Eastern lands, taking them from the Report of the United Planters' Association of the Straits for 1904:—

	Acres.
Malay Peninsula	30,000
Java	5,000
India and Burmah	5,000
	40,000

Ceylon and the Malay Peninsula are very likely about equal at present in their cultivated area.

As regards our exports from Ceylon, they commenced with 11 cwt. of rubber in 1889, but the Chamber of Commerce only began recording ten years later:—

* Seeds of *Hevea brasiliensis* were received at Kew early in 1876, and in August of that year 38 wardian cases with 1,900 plants were transmitted to Ceylon, where 90 per cent. arrived safely and were to be nursed and established in the Government gardens here for subsequent transmission through the Indian gardens to Assam, Burma, and other hot provinces of India proper.

1898......	2,792 lbs.	1902......	15,592 lbs.
1899......	7,910 ,,	1903......	44,798 ,,
1900......	8,233 ,,	1904......	77,212 ,,
1901......	9,072 ,,	1905 (½) ..	49,773 ,,

It only remains to afford an approximate value to the rubber-planted area in Ceylon, at this time. But that is a difficult matter. Taking the acreage at different dates, and apportioning a value such as we believe the owners would deem too low, we arrive at a total value of the rubber-planted land, and the cultivated rubber trees in Ceylon at this time of considerably over a million pounds sterling—that is an average of about £30 an acre, including newly-planted clearings or trees; but also including our oldest areas which are probably valued, in proportion to profit, at ten or twenty (?) times as much! It is impossible, in fact, in the present experimental, and, indeed, incipient stage of a great industry to arrive at a just value; but that the rubber-growing industry of Ceylon should already approximate to a total value of nearly 18,000,000 of rupees is a very notable fact in the planting history of the first of Crown Colonies.
—*Ceylon Observer.*

ENGINEERING IMPORT TRADE OF LOURENCO MARQUES.

A rather lengthy report has just been issued by the Foreign Office from H.M. Consul-General (Major Baldwin) at this important entrepôt. Lourenço Marques handled, in 1904, 23½ per cent. of the transit trade to the Transvaal as against 19 per cent. in the preceding year, owing to the cheap railway rates afforded, which are from 10s. to 15s. per ton cheaper than by other routes. Owing to the heavy shipments during 1903, the total transit trade was slightly less. There was a marked decline in imports from the United Kingdom, but general increases from Germany and other Continental countries. Major Baldwin lays much emphasis on a local condition "which has acted, and will continue to act with increasing severity to the detriment of British trade." The German East Africa line of steamers has a monopoly of the carrying trade between the competing European ports and those of the East Coast of Africa. Competiton by the Austrian Lloyd and by the British India Company's steamers is limited to a monthly service by each line, the English company suffering by transhipment at Bombay. The German company obtained its virtual monopoly by the aid of a heavy subsidy, and although freights may be regulated in agreement with other and indirectly competing lines, the existence of this "direct, regular, and efficient line of steamers. . . . . must tend to throw trade into the hands of the manufacturers to which the line belongs, and whose ports it is its principal business to serve." It is not to be wondered, therefore, that this, in conjunction with cheap inclusive freights from inland towns. Major Baldwin regards the outlook pessimistically and exclaims that "the gradual transfer of trade can only be a matter of time.". Still at the back of this pessimism there rests the fact stated a few pages further on that the actual tonnage of British shipping entering the port amounts to 854,027 tons, or 57 per cent. of the total. In 1903 66 per cent. of the tonnage was British, the decline in lead being due to a British decrease of 2·5 per cent. (a decline of over 22,000 tons), while the German tonnage increased by 51,638 tons.

As regards future requirements, exclusive of the Kaffir trade (in cotton, cutlery, &c.) the principal requirements during the next few years will be in connection with harbour works, docks, water and sewerage works and railways, and will cover all the machinery, sheds, pipes, cement, iron, timber and material used for the construction and equipment of such works. The local and the Transvaal firms are naturally in the best position to tender for these supplies, and the share of the orders which British manufacturers may obtain must depend upon the capability and energy of their representatives in South Africa. In this connection the writer of the report draws attention to the fact that the agencies for British manufacturers are in the hands of foreigners. "It is said that there is not much sentiment in business, but given only a slight margin between two articles there is probably sufficient sentiment to incline the agent to push the sale of those of his own country."

The following notes give particulars of the transit trade in the chief items among engineering goods in 1904:—

Sheet-Iron and Steel.—The total quantity dealt with amounted to 4,060 tons, valued at £41,992. Of this the United Kingdom supplied 3,000 tons, Germany 796 tons, Netherlands 146 tons, Belgium 78 tons, and United States 38 tons.

Rod, Block, and Hoop-Iron and Steel.—The imports were 6,422 tons in weight, valued at £82,973. The United Kingdom sent 5,358 tons, Germany 755 tons, the remainder being divided between Belgium, Netherlands, and the United States.

Iron Pipes.—Out of 4,091 tons, valued at £51,977, 2,630 tons came from the United Kingdom and 1,377 tons from the United States.

Galvanised and Corrugated Iron, weighing 10,990 tons, came, with the exception of 600 tons, from the United Kingdom. The total value was £137,031.

Machinery.—The trade under this heading is not catalogued with sufficient detail. Figures of tonnage are apt to be misleading in regard to articles of this kind. The total weight in 1904 was 9,096 tons, and the value £234,405. Of mining machinery, the United Kingdom supplied 241 tons, while Germany supplied 1,279 tons, and Belgium 147 tons. Cranes weighing 279 tons all come from the United Kingdom. As regards unspecified machinery, the United States sent 455 tons, Belgium 492 tons, Germany 2,374 tons, and the United Kingdom 3,713 tons.

HOME INDUSTRIES.

The Cotton Crisis.—The cotton industry in Lancashire, exceptionally prosperous during the last few months, is threatened with a wages strike. The operative spinners and the card-room hands, want the rise of 5 per cent. recently conceded to the operatives in the weaving section. Negotiations have been going on for some weeks without result, and the workpeople have decided to strike at the works on the 19th inst. unless the 5 per cent. be conceded. The decision of the masters not to give way has been determined by the adverse reports of the growing crop in the United States, and the consequent advance in price of ½d. per lb. A serious shortage in the crop is, however, hardly probable. The present American crop is not likely to be much short of fourteen millions of bales, and the least sanguine estimates of the new crop do not put it under ten millions of bales, which, with the enormous surplus from the crop now coming forward, should meet the world's requirements for 1905-6. The threatened strike affects not only the entire industry as such, but many subsidiary trades, such as bleaching, dyeing, and printing. Shipping and the railways would also suffer. The masters seem to think that a short stoppage, say for a month or six weeks, would not be altogether disadvantageous from their point of view. The short time last year, consequent upon the cotton scarcity, was followed by a period of great activity in the trade.

Labourers and Cottages.—Mention was made in this column last week of the cheap cottages at the Letchworth Exhibition. In the report of the Departmental Committee on the fruit industry the dearth of cottages in country districts is referred to as one of the difficulties in the way of the expansion of the fruit industry. But it is satisfactory to learn that many fruit growers take a broad view of their duty—and interest—in this connection. For example, Mr. Wise explained to the committee that at Toddington they had solved the cottage difficulty by building themselves thirty cottages having been erected at an average cost of £450 a pair, and let for £5 per annum each, which meant that the landlord received practically no interest upon the capital expended. But, said Mr. Wise, it was worth while "to fit up a good cottage to have a good man if they could get one," and he added they regarded it as part of the business of the fruit farm. It is to be remembered that the District Councils have the power to build cottages with the assent of the County Council, under the provisions of the Housing of the Working Classes Act, 1890. Hitherto little has been done in this direction, the time allowed for the repayment of loans being so short as to render the rent which had to be paid prohibitive to working men. But now that the provisions of the Housing of the Working Classes Act, 1903, authorise the extension of repayment from 60 to 80 years more should be done under it.

The World's Supply of Cotton.—Not much progress is being made in the cultivation of cotton in countries other than the United States. The movement for the promotion of cotton growing in West Africa, initiated at the memorable meeting at Manchester in May, 1901, has not as yet done very much to quicken cotton production in those parts In the West Indies the export has doubled during the last five years, but is still very small. It is only in India that there has been really large expansion in cotton cultivation. Egypt is practically stationary, and the world is still mainly dependent upon the United States for its supplies of cotton, as the following tables, giving imports of cotton into the United Kingdom, show:—

	1900.	1901.	1902.	1903.	1904.
	Cwts.	Cwts.	Cwts.	Cwts.	Cwts.
Sierra Leone	...	...	...	26	212
Gold Coast	184	20	...	150	363
Lagos ..	221	105	56	4,418	3,443
Niger Protectorate ..	...	...	20	...	2,626
West India Islands	3,892	3,124	3 747	6,897	7,374
India. .	311,841	335,480	289,923	726,963	846,471
Egypt...	2 789,722	2,519,030	3,168,697	2 642,017	2,899,235
United States	12,190 169	13 221,303	12,177,136	12,153,019	13,310,446

And it must be remembered that whilst a few years ago the American consumption of cotton was quite insignificant, America now consumes nearly a third of her produce.

Blackberries.—Until very recently the commercial value of blackberries was strangely ignored. Growing freely in almost every part of the United Kingdom, and in some places, as in parts of Wales, nearing the size of a gooseberry, an excellent fruit, no no serious attempt had been made to improve, collect, and send them to the London market. But during the last year or two more attention has been given to them, and it looks as if they will soon be thoroughly exploited. When of good quality they fetch a price that must leave a handsome profit. Last year they were sold in London at 9d. and 1s. a pound, and it is said that this year over fifty tons will be disposed of to the public by London firms alone. There will be large and regular consignments from Kent, Derbyshire, and other blackberry-growing localities over the United Kingdom. Large shipments will be sent from Ireland to West of England ports, and it is expected that at least 50 per cent. more will come into the market this year than last. This new development deserves to be encouraged in every way.

A Novel Carpet Factory.—During the last two or three years the failure of the Scottish herring industry has brought great distress to many Highland fishing villages, and with the object

of lessening it the Duchess of Sutherland suggested a carpet factory which should utilise the wools turned to so many purposes in the Highlands. An experiment was made in the village of Helmsden, a fishing hamlet of a few hundred inhabitants in the extreme south-east of Sutherlandshire. An expert was engaged to teach the young women of the place the manufacture of carpets, and the first product of their looms is a carpet now on view at Messrs. Waring's. It carries a free and flowing scroll design accentuated in the vivid natural colours obtained from vegetable dyes. The carpet resembles an English Turkey, although its surface is a little more firm, and it is believed that when the looms are fully at work the price of similar carpets will not be high. They are to be known as the "Sutherland," and if only they can win public favour the benefit accruing to the Sutherland villagers should be great and lasting.

Receiving Orders and Trades.—In the Annual Report by the Board of Trade, under Section 131 of the Bankruptcy Act, 1883, there is an interesting list of the number of receiving orders and administration orders, under Section 125, made in the principal trades and occupations during the years 1903 and 1904. From this list it will be found that more of these orders are made against builders and less against pawnbrokers than any other class. Of the 4,546 made in 1904, 313 were applied to builders, and only 3 to pawnbrokers. Next came grocers, against whom 281 orders were made, publicans following close with 262, farmers, bakers, butchers, greengrocers, boot and shoe manufacturers and dealers, drapers and haberdashers, tailors, follow in the succession here given, officers in the army numbering 24 and Clerks in Holy Orders 8. Fifty-eight prosecutions under Section 166 of the Bankruptcy Act, 1883, were ordered during the year and of these 47 resulted in convictions. The largest number of charges were for obtaining to credit to the extent of £20, and next for not making full discovery of property.

GENERAL NOTES.

TEA AND INDIGO IN JAVA.—Some months ago it was pointed out in the *Journal* that Java might soon become a formidable competitor of India and Ceylon in the tea markets of the world. The figures found in Mr. Consul Fraser's report on the trade of Java in 1904 supports this statement. During the year the production of tea in the island increased by over 3,000,000 lbs., and a large area of new land was laid out for tea culture with Assam tea seed, which insures a further increase of quantity to be disposed of in the near future. The exports to the Netherlands and Russia show considerable advances, although, owing to the war, teas for the latter country were shipped *viâ* Europe, instead of *viâ* Dalny and Siberia. The growth of the tea exports are shown by the following figures, which represent the exports for the years named:—1899, 12,841,720 lbs.; 1901, 16,750,872 lbs.; 1904, 25,375,691 lbs. Last year the Netherlands took 13,102,916 lbs. of the total quantity exported, and the United Kingdom 9,918,408, Russia being third with 1,263,007 lbs. The war between Japan and Russia has apparently closed the markets of these countries to Java indigo. Planters have, therefore, had to ship their productions to the Netherlands, where only the better qualities have been able to compete successfully with synthetic indigo. In view of the difficulties experienced during the last few years in finding markets for Java indigo, it is feared that the acreage under cultivation will have to be largely curtailed.

THE FAILURE OF RUBBER PLANTATIONS IN MEXICO.—Mr. L. J. Jerome, H.M. Consul for the Consular District of Mexico, in a report dealing with the trade and commerce of his district, deals among other matters with rubber cultivation in Mexico. It is stated that the numerous plantations have not been successful as dividend earners, and that much harm has been done to the genuine concerns by the operations of a number of fraudulent undertakings having their headquarters in the United States. Mr. Jerome says:—"It is absurd to anyone who is acquainted with the labour of climate of the hot lands of Mexico to suppose for a moment that large profits can be made out of tropical plantations. In the case of genuine concerns, a comparatively small return can be expected for the capital outlay; a much smaller return than can be obtained in safer and less speculative investments in Mexico, but when the prospectuses and literature of tropical agricultural companies promise wealth in a very short time it is safe to assume that the undertakings should be left alone."

FOOD IMPORTS.—Amongst the food imports into the United Kingdom milk and cream, other than in the prepared form, are not generally included in the public mind, yet there is quite a considerable import of these articles. For example, the quantity of milk and cream exported from Cherbourg to Southampton during 1904 was as follows:—Cream, 49,848 gallons; new milk, 9,010 gallons; prepared milk, 44,764 gallons. A large trade is done from the same port in early potatoes, the actual export of early potatoes to the United Kingdom in 1904 being about 37,000 tons. The potatoes on the early market are put into trays (called boxes), writes Mr. Consul Loftus, in his report on the trade of Cherbourg (No. 3440, Annual Series) in late autumn, where, being arranged with the eye upwards, they sprout, and provided the light is allowed to fall upon them, a healthy green sprout, which can be planted in March, comes up at once, permitting much later planting than would otherwise be the case. This is the Jersey system.

NOTICES.

EXAMINATIONS.

The results of the Intermediate Examinations (Stage II.) will be published to-day (Friday), and copies for distribution to Candidates will be sent to all Centres next week. The results of the Elementary Examinations (Stage I.) will be published early in September.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

SOME ASPECTS OF ANCIENT AND MODERN EMBROIDERY.

By Alan S. Cole, C.B.

Lecture II.—Delivered May 8th, 1905.

Whilst the Bayeux Needlework is, without doubt, the most important piece of secular embroidery which we know of, done in France or England during the eleventh or twelfth centuries, available evidence concerning English decorative needlework of the twelfth, thirteenth, and fourteenth centuries points to a preponderance of such as was in use for ecclesiastical purposes; and this may be accounted for, in some degree at least, by the facts that the Cluniac monks were enjoined under their rules to pay special attention to liturgical splendour, and that monastic establishments, many of which were under the Cluniac rules, were almost the only places in England at which there was sufficient organisation for producing such artistic work as decorative embroidery during the period in question. Conditions favourable to work-rooms of a purely secular or trade character did not arise until the thirteenth century. That they did arise, may be said to be due in great part to the eventual infusion of Norman habits of order into the English people, who thus became sensible of the value of social and political organisation, of law, method, and enterprise. In due course, then, under such conditions, it is not improbable that embroidery became a home occupation for wives and daughters especially, of men engaged in other crafts and callings; and we get perhaps a suggestion of this phase in the practice of the art characteristic of the thirteenth century from specimens of it, which have a marked affinity in ornamental design to that of scrolling metal work. Goldsmiths, who found it worth while to settle in some of the comparatively few important towns, carried on their work independently of monastic workshops, and probably supplied the gold thread, in some cases gold wire, with which much embroidery was made at the time for military, civil, and church ceremonial purposes. An early MS. mentions, "Goldsmythes furste and ryche jeweleres: And by hemself crafty Broderes." This appears to indicate the existence of some sort of kinship, as it were, between such craftsmen, and I will refer shortly to a definite instance of actual co-operation between such craftsmen in making an important bit of work.

But before doing so I wish to show you a slide from an engraving of the vestments reputed to be those of Thomas à Becket, which are preserved at Sens. The ornament of the mitre, and near the neck and shoulders of the cope, is of a scrolled metal style, and is embroidered in flattened gold thread. Very like it is the gold thread embroidery upon remains of faded silk which were found in an early thirteenth century tomb at Worcester, the tomb of Bishop Walter de Cantelupe.

More graceful in design, but of the same kind of needlework, are the fine open scrolls, encircling lions, on this slide (Fig. 9). This is part of some thirteenth century vestment, but from the absence of sacred symbolisms it serves also to suggest at least a style of orna-

ment for secular work at that time. The examples of such embroidery are rare.

King Henry III., as is well known, was an active patron of his country's arts, not merely of those followed under ecclesiastical direction, but of those independent of it, and one reads of His Majesty issuing instructions in 1244 that Edward Fitz-Odo, the son of Odo, a famous gold worker at Westminster, should make a dragon in the manner of a standard or ensign of red samit (or silk), to be embroidered with gold, and "his tongue to appear as though continually moving, and his eyes of sapphire and other stones." This clearly establishes such an inter-relation of art-crafts, as I allnded to above, and proves the employment of a

FIG. 9.

GOLD THREAD ENGLISH EMBROIDERY. THIRTEENTH CENTURY.

goldsmith, a jeweller, and a broderer upon a single important bit of work. On another occasion the King calls upon John de Somercote and Rogeri Scissori—art workmen in Lichfield—to produce richly embroidered silken robes, tunics, &c.

Upon this next slide we see gold thread scroll-work in combination, with figure subjects minutely stitched in silk embroidery. This is the front of a thirteenth century embroidered chasuble, the shape of which has been cut and altered since it was first made. The sacred figure subjects set within the four-lobed panels were doubtless derived from some MS. illumination and are admirable for the simplicity, distinctness, and apparent earnestness with which they are expressed. The combination of scrolls, panels, and figures is distinctive as a fourteenth century type of design for embroidery and worth noting. In old documents, inventions, and records of the thirteenth century for instance, entries concerning "opus Anglicum," "opus Plumarium" and the like often occur; and although it has grown to be a custom to accept "opus Anglicum" as a title peculiarly identified with fine split-stitch or chain-stitch embroidery of such sacred subjects as those we have just seen, I do not think that there is any more valid authority for accepting it in this way than there is for assuming that "opus Plumarium" is a long and short or feather stitchery of the thirteenth and fourteenth centuries. As I mentioned, last Monday, plumarius was the trade title of the Roman embroiderer; so that "opus plumarium" should mean embroiderers' work generally. The fame of English ecclesiastical embroidery was certainly very considerable in the thirteenth and fourteenth centuries. Many fine examples of it were sent abroad, sometimes as royal gifts, at others in response to definite commissions for vestments of "opus Anglicum." Still it may be well to note that a century or two before the English needlework had attained this celebrity, it appears that the typically English illumination of MSS. was also called "opus Anglicum." How much the famous embroidery owes to equally famous contemporary illuminations is a point which seems to me to be capable of a good deal more elucidation than that which I can try and offer to-day.

I have chosen one or two specimens of the kind of embroidery which seems to be fairly well authenticated as English of the thirteenth and fourteenth centuries, and also of one or two examples of MS. illumination of the same time. These may serve to show some relation of designs for MSS. to those for embroideries.

In describing a finely illuminated MS. of the thirteenth century, well-known as the "Tenison Psalter," the late Sir Edward Bond pointed out that in the course of that century the arts of painting and illuminating were becoming secular professions followed outside the cloister. To a similar extent embroidery must have been done also outside the cloister; but it would be difficult to hint at all satisfactorily how far the embroideries we are about to look at were made in monasteries or outside them. In any case the designs are clearly the work of

trained and versatile draughtsmen, whilst the needlework exhibits a technical finish, which, without offence to modern English workers, is unrivalled by their work as a rule.

I hope, from what I have said, that it will not be difficult for us to picture to ourselves that frequent co-operation must have been the rule between the draughtsman and the embroiderer—that is to say, between the illuminators and possibly their wives and daughters or those of other artistic craftsmen, such as goldsmiths.

In the fourteenth century, guilds for regulating the conditions of their work were beginning to be formed by the craftsmen themselves, and such organisation seems to have been a secular counter-move to the dissensions between the various religious bodies. It is claimed that, as early as the thirteenth century, a craft guild of embroiderers existed in London. This, however, may be doubtful, though from a legal document dated 15th November, 1293, belonging to the present Broderers' Company, it appears that the existing Broderers' Hall in Gutter-lane stands on a site then occupied by the workshop of William de Herslake—a saddler—which was close to the tenement of one Adam, a goldbeater. We may, perhaps, imagine that William de Herslake sometimes undertook to produce saddlery and horse-trappings decorated with embroidery and, if so, that Adam the gold-beater may have helped in procuring the gold thread or wire required by Herslake for such a purpose. However this may be, it is quite certain that, of the existing charters of the Broderers' Company, the earliest was granted by Queen Elizabeth in the sixteenth century, or some 300 years later than the times of William de Herslake the saddler and Adam the gold-beater. Amongst the Company's interesting historic possessions are two cups, one given in 1606 by John Parr, who was embroiderer to Queen Elizabeth and James I., and the other by Edmund Harrison, embroiderer to James I. and Charles I. The Company now-a-days encourages the instruction of women in embroidery by means of scholarships, which are tenable at embroidery classes conducted in various London technical schools.

Let us, however, return to the thirteenth and fourteenth century English church work.

We begin with the famous cope in the Victoria and Albert Museum known as the Syon Cope. A full description of it is given in the late Dr. Rock's "Textile Fabrics in the South Kensington Museum." The particular points upon which I wish to lay some stress are:— First, that the surface of the cope as displayed in this slide is entirely of needle-stitched embroidery. The ground is as elaborately stitched as the figures upon it. There is no employing of a rich satin or velvet and then embellishing it with occasional embroidery. As I have said, all that we see here is pure needle-stitched embroidery. From the technique of the needlework, let us turn to the design which consists of a sort of tracery or diapering, composed of overlapping quatrefoils. Simple diaper and trellis patterning was much in vogue in the thirteenth and fourteenth centuries. Within the quatrefoils and interspaces are various figures. In the highest central quatrefoil is Christ, crowned as a king, seated with the Virgin Mary. Below this is the Crucifixion. The single figures consist of the Apostles and of seraphims with crossed wings, a device which appears in much earlier illuminations. These figures stand out clearly in definition or silhouette against their backgrounds. Most of them have a slightly curved attitude.

Now some corresponding characteristics will be seen in the next slide, which is taken from a page of the illuminated MS., known as Royal MS. 1 D. 1 in the British Museum. Dr. Warner, keeper of the Manuscripts, who has very kindly given me valuable information in the course of the enquiries I have made, calls attention to an interesting coincidence: that one William of Devon was the writer of this MS., and living at the same time was one Master William, a painter to the king, and named in the Close Roll of Henry III. 1251-2. Whilst there may be no direct evidence that the King's painter actually illuminated the MS., it is not wholly improbable that he may have done so. The point, however, is not of serious importance, it is merely suggestive in connection with secular illuminators.

The page of illumination before us gives us the coronation of the Virgin, the Crucifixion, with the Virgin and St. John on either side of the Cross; seraphims with crossed wings, and St. Peter and St. Paul. These are all of rather more rigid appearance than the same subjects and figures in the Syon Cope, but there are resemblances in details between the two, sufficient, I think, to convey a sound suggestion of co-operation between illuminators and embroiderers in production of such church vestments. Such resemblance is stronger, I think, between this illumination

and the cope of opus Anglicum, known as the Madrid Cope, of which a coloured illustration is on the table.

Another cope, of slightly later date than the Syon Cope, is known as the Ascoli Cope, and has been the subject of much recent discussion. Its embroidery is as elaborate as that of the Syon Cope, and entirely covers the outside of the vestment. The underlying scheme of its design depends upon a repetition of separate roundels, which are cusped, containing figures representing sacred events relating to early and later Popes. We see only four of these roundels.

The next slide, however, gives us a full view of the cope. Taking the series of roundels horizontally, we have in the upper one a head of Christ in centre, and I ask you to note some special features of it—the arrangement of hair falling at the back of the neck; the shaping of the beard; the high forehead and the long nose. On each side of the Christ are martyrdoms of different Popes, such as St. Clement, St. Peter, St. Corneille, St. Marcel. The middle horizontal series has the Crucifixion in the centre, and right and left of it various teachers of the Church—St Sylvestre, St. Gregory, and others, each accompanied by two Bishops: the lower series consists of the Virgin and two angels in the centre and two Popes on either side, the four Popes being Innocent IV., Alexander IV., Urban IV., and Clement IV., who succeeded one another in the Pontificate from 1243 to 1268. A coloured illustration of this cope is exhibited in a frame.

The use of roundels and variously shaped panels enclosing figure subjects occurs in English illuminations of the thirteenth and fourteenth centuries, and the instance of shaped panels which I show is supplied by part of a page of a Psalter of the early fourteenth century. The style of the figure drawing, broadly speaking, corresponds with that of the Ascoli Cope, although the subjects are different. The face of Christ, however, has many points of resemblance to that on the Ascoli Cope, the high forehead, the long nose, the shape of the beard, &c.: suggestive of the relation between the work of the illuminator and that of the embroiderer.

Another type of embroidery design is given in this slide from a fourteenth century cope of red satin, worked with the same kind of needle-stitched embroidery as that of the previous copes. In this, however, the satin plays an important part in the design, as a ground to the symmetrical scrolling branches of the Jesse tree, the various figures in which are similar to those in the Syon Cope. There is a good coloured illustration of this Jesse tree cope in the room.

Specimens of secular embroidery of the fourteenth century are rare. One, entirely different in work from those of the Church vestments just seen, belongs to the Victoria and Albert Museum, and is a hanging of patchwork in coloured cloths. (Fig. 10). This method of decorative needlework is well suited to the rendering of broadly-treated designs. The example before us is called French; however, I see no particular reason why it may not equally well be called English. Forms of different shapes are introduced into it; at the same time, breadth and simplicity in treatment so suitable to the method of patchwork, are distinct features of this specimen. The late Dr. Rock, in describing it, suggested that the design probably represents incidents corresponding to some in the legend of Sir Guy of Warwick, an Old English metrical romance, written in the thirteenth century. The costumes depicted here are of a century later. The drawing and grouping of the figures and their surroundings appear to be such as one would be likely to see in an illuminated MS. of the legend.

Failing to find some contemporary drawing or painting of English embroiderers at work in the fourteenth century, I have had a slide made from a fresco by Ambrogio Lorrenzetti in the Palazzo Publico at Siena between the years 1337 and 1339, of an ideal prosperous town at that period. With some modifications in the architecture, it may serve to give approximately some idea of what would have been going on in an English country town—say Canterbury, for instance. To the left we have a boot-shop and men at work, beyond it a school; then a grocer's or wine-shop; in the background two women at needlework near the small alley, up which are passing mules bearing bales of wool packs, &c.

Now the three or four specimens of English thirteenth and fourteenth century embroidery, which we have seen, serve, I think, to convey a fair idea of the standard of technical finish attained in a time when its fame abroad was very considerable. However, soon afterwards it began to deteriorate, and it may be difficult to account for this. Both illuminating MSS. and carrying out embroideries from designs by illuminators were apparently becoming professions, to some extent at least, outside the

religious houses in which the main practice of such arts had been fostered. But it would seem that this outside or secular practice of the arts had not taken effective root, so that when the influence of monastic establishments began to weaken, as it did, the interests, of a comparatively minor art such as embroidery, suffered. The deterioration in English embroidery coincides with a period when conflicts were constant between secular and religious forces and when foreign and civil warfare was the rule, and yet it is interesting to note that progress was nevertheless being made in developing material resources, and manufactures of utilitarian value, however much the nurture of the decorative arts may have lapsed. The deterioration in embroidery is accompanied too by change in style of the ornamental and decorative elements used in the designs for it. Some part of this change may, I think, be traced to the effect brought about by the introduction into this country of foreign finely-woven ornamental stuffs, brocaded silks, satins and velvets, the like of which certainly were not, and probably could not, have been made here. Of many kinds and varieties, the designs of these imported fabrics were naturally attractive. They were more easily obtained than the less quickly produced embroideries, and so coming into general use amongst the wealthy members of the community, by the Court and the Church, they in large measure superseded embroideries. For embroidery to maintain any sort of position in such circumstances of competition, change in its ornamental appearance and in the amount of labour bestowed upon it was inevitable; and so we find that handsome woven stuffs were often adopted by the embroiderer as the ground-work for his enrichments. Embroidery used in this relatively economical and sparing manner came to play an almost subordinate part to fine-weavings: its designs gradually became flavoured with characteristics of woven ornament. Thus embroidery ceased to possess the charm of its earlier richness and individuality and descended to a diminished position in æsthetic importance. The progress of this change is often indicated in English Church embroideries made throughout the fifteenth century. Probably the greater number of church vestments consisted of foreign silks and velvets, rather sparsely sprinkled with embroidered ornaments and bordered with effigies of saints and such like, more often singly than in groups as in the earlier embroidery.

FIG. 10.

PATCHWORK: POSSIBLY ENGLISH OF THE FOURTEENTH CENTURY.

An example of this class of work is now thrown on the screen. It is a cope of rich purple velvet. The border, or orphrey and hood, are of embroidered figures; on the hood is a seated figure of God and on the orphrey are single figures of apostles and saints under Gothic canopies. Upon the velvet ground in the centre is the Assumption of the Virgin, above are two fleur-de-lys and below two Tudor roses. Three seraphims are symmetrically arranged about these devices, and beyond

again are various floral ornaments. All these details have less of that clean-cut definition and simplicity which are so characteristic in fourteenth century "opus Anglicum;" further, the epical or story-telling interest of the figures is small, and repetition of details is noticeable in the composition of the pattern. However, this is a good specimen of late fifteenth century embroidery.

In designs of later English embroidery we shall notice a still further decline in simplicity of treatment and epical or story-telling interest, whilst repetition with almost geometrical symmetry is the principal basis of the patterns. Hence the earlier imaginative and versatile MS. painter seems to have become succeeded by a somewhat mechanical and not very inventive draughtsman, who was more or less under the influence of repeating patterns as displayed in woven materials.

Although English church embroidery was almost dead in the sixteenth century, secular embroidery in England seems to have had some fair vitality. It was used a good deal in the costumes of the Court, and many of the modes of its use and characteristics of its ornament came from foreign sources into this country. For example, the work of Holbein as an ornamentist contributed to English acquaintance with an Italo-Flemish style of arabesque ornament which is reflected in the gold thread embroideries of King Henry VIII.'s costumes, so frequently shown in Holbein portraits. In another way professional embroiderers, such as were employed by Queen Elizabeth and James I., must have been influenced by the ornamentation of Chinese and Indian embroideries and printed cottons, newly brought into England towards the end of the sixteenth century. Repeated scrolling stems bearing and encircling flowers, birds, &c., are prominent features in many such Oriental works, and furnish a comparatively lively contrast to the sedate and balanced ornament which in large part had been derived during the earlier part of the century from architectural panels and friezes of an Italian Renascence type. Then again, books of patterns for embroiderers were published first of all in Venice and Paris, and came into circulation during the sixteenth century. One of them was compiled by Matthew Mignerak, an Englishman, described as a most expert worker in all sorts of linen work. Beyond this, one may note the influence of British affection for flowers, fruits and such like, which had long before expressed itself in manuscript illuminations, and now amongst other ways, showed itself in adapting such subjects as ornamental devices in embroidery.

A fine example of the class of the conventional arabesque embroidery which had a vogue in sixteenth century costume, is shown in this portrait of Charles IX. of France, painted by François Clouet, about 1570 (Fig. 11). The daintiness and intricacy of the stiff inanimate ornament are well displayed in the bands of gold embroidered work, the decorative value of which is enhanced by contrast with the intervening ground of plain velvet. The whole costume clearly exhibits the skill of a good professional designer. Such men were more numerous in France than in England. Similar ornament was carried into embroidered hangings and curtains. It is a style of design that has more academic accomplishment so to speak, than the peculiarly English style introduced into embroidery in the sixteenth and seventeenth centuries; indeed the English style exhibits many breaches of academic rules for the composition of ornament, and in this way points to an absence of that influence which, in Italy, for instance, arose from the traditions of continuous practice in the decorative arts. The English style attracts attention by reason of its independence and quaintness in conceit, a quality perhaps in some relation

Fig. 11.

Charles IX. Portrait by François Clouet.

to that of the conceits of Jacobean and Stuart poetry, which is said to have arisen from an aim of its writers to amuse by forcing the contrast between ideas and objects apparently remote and diverse. If such a suggestion is somewhat far-fetched, it does not clash with what, I think, was the fact, that there was a prevalent taste for certain extravagances, and, however well they may have been turned in literature, they were more absurd when represented in embroidery.

FIG. 12.

QUEEN ELIZABETH. PORTRAIT ASCRIBED TO ZUCCHERO, AND BELONGING TO THE DUKE OF DEVONSHIRE.

Portraits of Queen Elizabeth in one or other of her historically numerous and fancifully-varied dresses give one, I think, impressions of the better achievements of which English embroiderers were capable in her time. Here, for instance, is one ascribed to Zucchero, belonging to the Duke of Devonshire (Fig. 12). The Queen's underskirt is embroidered, perhaps, in cross or tent stitch, with a medley of plant, animal, and bird forms. There seems to be little feeling for balance, congruity, contrast, or ornamental arrangement, and even the colouring does not contribute much towards bringing the medley into harmonious unity.

The dress in Her Majesty's portrait at Hatfield is another instance of extravagance in conceits. The cloak is spotted with embroidered eyes and ears, along the sleeves are twisted snakes, and on the body of the dress is an orderly arrangement of floral sprays. At Hampton Court there is a portrait by Zucchero, which, if not of Queen Elizabeth, is of a lady of the period. Her dress is embroidered with continuous scrolls of fine stems, bearing all sorts of flowers. In between the scrolls are birds and butterflies and so forth. Another portrait of particular value for the careful drawing of the embroidery shown on it was exhibited under No. 269 at the Tudor Exhibition a few years ago. The embroidery was in black silk principally, and the pattern was of scrolling and intertwisted stems bearing various flowers and fruit shapes. In patterns of such scrolls there is more order and scheme than in the heterogeneous medleys previously referred to; and this order is, I fancy, a reflex in pattern designing of that with which English embroidery designers and workers were becoming acquainted, through late sixteenth century Italian weavings more especially, and through Oriental and Chinese embroideries gradually imported at the time. In a frame is a specimen of an ordinary Italian ornamental worsted weaving—the patterns of scrolls and pomegranates, &c. In another frame is practically the same class of pattern, done in black and gold thread English embroidery.

This slide also shows us something of this order or scheme of scroll design, strongly flavoured, however, with the English characteristic conceits of curious flowers and insects, embroidered on the linen jacket in coloured silks, the scrolling stems being of gold thread.

In the next slide we have a similar pattern of daintier scrolling stems, with flowers and leaves on a smaller scale, all, however, embroidered in coloured silks. In a frame is an interesting modern adaptation of this sort of pattern. It has been made by Miss Fellowes, of Birmingham School of Art.

Of a different character of work is the raised and padded embroidery, which was much used in James I. and Charles I. and II.'s times for boxes, mirror frames, &c. Medley of heterogeneous devices is the keynote of style in design for such work. This, as we have seen, arose in the Elizabeth period, but the class of raised and padded embroidery grew into greater vogue during the two succeeding reigns.

I have had an enlargement made of part of the lid of a Stuart box or casket in order that

the great skill and regularity of needlework may be seen. King Charles I. is seated beneath a canopy; his Queen is advancing towards him. Her dress is embroidered with a medley of floral devices. The curtains of the tent are decorated with the scroll and blossom pattern on a large scale, much the same as in the Elizabethan jacket we looked at. All about are odd disproportionate objects, absurdities, no doubt, yet factors in what has become a recognised style of embroidery design. Amongst the curious details are acorns rather larger in size than the pears near at hand; a moth or butterfly near the Queen is bigger than her head, and even than the dog above her, and so on.

A few years later in date is a toilet box or casket, covered with white satin, upon which raised and flat embroidery has been worked. This slide gives us the front of the box with one of its doors, or flaps, thrown back so as to show the flat flower embroidery of the inside in contrast with the raised work of the outside. Along the lid are quaint plant forms, a butterfly or two, and a rabbit and a squirrel. The sides of the box, which we do not see, are decorated with curious figures illustrative of Narcissus, Venus and Adonis, Apollo and Daphne, in Stuart dresses. The ornament on the lid of the box is arranged with intention and order; at the centre is a frame with a portrait, and balancing each other at the corners are grotesque birds, extravagant compounds of birds, shells, and butterflies, an indulgence in quaintness or conceit, which, however, was more vigorously expressed in marginal illuminations of MSS. some three hundred years earlier. The feeling for balance or order in arrangement may perhaps be considered to have been derived from Oriental work of later date. The skill of stitchery, which is admirable, is native. Deficient as we may have been in the art of ornamental design, our stitchery has been good; and, in connection with this, the numberless samplers of the seventeenth and eighteenth centuries which have recently turned up as valuable documents in the history of embroidery, show, as a general rule, how assiduously girls practised the working of many sorts of fancy embroidery stitches, not to prove the peculiar application of them to definite schemes of ornament, but rather to exhibit variety in beautifully taken needle stitches.

Towards the latter part of the seventeenth century the stitchery in single specimens of costume and hangings is often comparatively simple and uniform in character, however much the details of the ornament may be varied. For instance, in this quilted bodice almost the whole of the embroidery is of chain-stitch only. The flowers, leaves, and birds are fanciful in shape and treatment, much of this being borrowed from some Indian or Persian pattern: the distinct symmetry in the arrangement of these details is also derived from Indian or Persian patterns of the time.

Here, now, is a colour-printed cotton bed-cover from Masulipatam, which is but one type of many variations played for centuries by Indian or Persian Mohammedan pattern-makers upon a favourite motive inspired by the spreading branches of a tree, with birds seated

Fig. 13.

Cotton Curtain of English Seventeenth Century Crewel Work.

amongst them, and the ground busy with undulations and animal forms. In this particular print the design is a masterpiece of symmetry and ingenious interlacement, the branches well marked, and the background powdered with delicate leaf forms.

We can sympathise with an enthusiastic English embroiderer of the seventeenth century, who, upon seeing such a thing for the first time, would naturally almost become subject to the influence of its novelty, and so take ideas from it.

This portion of an English crewel embroidered curtain will perhaps illustrate my meaning (Fig. 13). The inclination to observe order and balance in arranging the details of the design is shown. There is well marked contrast between the stems and branches, and the small leaves, &c., powdered over the background. There are quaint bird forms;

the twisting tree stems grow from undulations or mounds, in which occur odd birds and animals. There are turns and touches which announce the English embroiderer, notwithstanding the underlying Orientalism of his design; and so we have a product which contributes to founding what in after years becomes a recognised "style," but is neither pure Oriental nor pure English. It was, however, sufficiently attractive at the time to call into life some trade in English worsted embroideries on linen, cotton, and canvas for curtains, cushion and furniture covers from the times of William and Mary into a good part of the eighteenth century.

In a corresponding way, trade in embroideries for costumes flourished and met a range of popular demand far wider than that of the mediæval Church or the Plantagenet Courts. This slide from an engraved portrait of King George III. supplies us with a typical instance of the kind of gold-thread embroidery on such a coat and waistcoat as was worn by His Majesty on state occasions. In formality and limited variety of pattern the embroidery has some affinity to that of many present-century Court dresses. The eighteenth century style of patterns in the embroidery on men's ordinary costume was chiefly French, owing much of its characteristics to naturalistic floral sprays and garlands, ribands, &c., such as are profusely displayed in silken weavings of the Louis XV. period: and a principal feature of the style in connection with costume is the repetition of the same details—the same bunches and sprays—along the edges of coats, and on the flaps of pockets.

The next slide is from an English dress-coat and waistcoat of fancy velvet, embroidered with coloured silks, and we notice the repetition of the same bunches of leaves and blossoms, as a ruling principle in the design or composition of the embroidery here.

It would, I am afraid, take us too far away from the particular considerations we have yet to deal with, to attempt any analysis of changes of fashion and taste, to trace their effects upon the course of the art of embroidery in this country, and to account for the decline in the employment of embroidery, whether for costumes or other decorative purposes, which appears to have occured during the first half of the nineteenth century. In any case I think that it would be seen that the ornamental designs, whether for such coloured or plain white linen embroidery as were made for general use, more than ever ran in a groove similar to that of patterns mechanically printed or woven, in which repetition of devices is unavoidable. Any efforts towards a more independent style which would give better opportunities for displaying the intrinsic merits of embroidery as an art handicraft, were few and far between: there seems to have been little or no public taste to encourage them, little appreciation in fact of individuality in such branches of ornamental art.

However, after about 1860 a change, which had been aimed at, does begin to appear. International exhibitions had been held at home and abroad; there were popular movements, due to private and to State enterprise, to direct attention to the study and practice in this country of ornamental art in its relation to taste in the production and use of things of everyday life: Schools of Art aided by Government in different parts of the country had been at work for some few years; Ruskin had lectured and written; William Morris was working in concert with Burne Jones, and influencing taste in many branches of artistic construction and decoration, including of course ornamental textiles, tapestry-weaving, and embroidery; two or three schools or societies were started for encouraging embroidery, the first one I think being under the presidency of Princess Christian, and another under Princess Louise (Duchess of Argyll), and from these emanated embroideries of individual character, some from designs by Burne Jones, Walter Crane, and others. Exhibitions of ancient embroidery were held, an Arts and Crafts Society was organised in London with offshoots in the country, a Home Arts Association of work centres throughout the kingdom came into being, and within the last twenty years or so, local authorities and others have formed classes and schools for systematic technical instruction, all of which have been agencies to develop general taste in working and using embroidery. These forces of varied character have been, I think, more favourable to independence and individualism of work than to reviving such uniformity and conventionality as seems to have prevailed in (say) English decorative art under monastic influences. Probably too it may be said that our modern British conditions are less restrictive than those of academical *régimes* which have obtained in France, where Central Government institutions, since the time of Colbert at least, have more or less set up official standards of art workmanship and manufacture. It is pleasant to find that much

of our modern embroidery excites the admiration of critics abroad, who appear to detect in it merits of vitality, and taste, of which we ourselves may not be entirely conscious. As may be gathered from what I have just said, the operations influencing embroidery in the kingdom are many, and indeed far too many for me to attempt to give illustrations of them in any adequate way. The most I can do now is to show only a few slides in respect (1) of a class of embroidery done for general trading, (2) of embroidery done by students in art schools as samples of their taste and skill, and (3) of embroidery done for special occasions by well-trained hands from designs by decorative artists.

Embroidery for general trading is executed sometimes in the homes of the individual workers employed; and sometimes in workrooms in which the hands employed are brought together under supervision. Close instructions are issued in respect of the work required; and the embroideresses are not called upon or expected to show any originality in taste or work. Their labour becomes specialised; indeed, it is said to such an extent, that the majority of the workers appear to be unable to use their skill in stitchery for mending their own clothes. Should the drafts of the pattern supplied to them be incomplete, they are not sufficiently acquainted with pattern drawing to be able to make good a deficiency. A considerable quantity of the embroidery made for general trading is in the nature of partly worked samples, ultimately sold at embroidery shops to dilettante embroideresses. The designs for these things aim at being popular, not very difficult to work, showy in effect and not necessarily in conformity with any particular canons of composition.

Here, for instance, are four specimens. The device or pattern is indicated on each one, either drawn or painted, and enough of it is embroidered to serve as a guide for its completion. Two of the samples have natural branches of flowers placed on them without ornamental treatment; the other two, as regards their details, seem to have some tendency towards what might be called ornamental treatment, though the choice of details may not exhibit an exercise of much judgment. The workrooms in which such samples are produced in hundreds, for the spring and summer seasons particularly, are apparently well lighted and well equipped, as may be seen from the illustration which has been kindly supplied to me (Fig. 14). All the work is being done in wooden frames. When it is a question of heavy gold thread embroidery on cloth or velvet, as for uniforms, iron frames are necessary to ensure proper tension of both the material and the embroidery worked upon it.

From trade work I pass to that done by students in schools of art, who produce it in connection with the technical studies they may be undertaking. On this slide is a design made a year or two ago at the Belfast School of Art, accompanied by a part of it worked out in embroidery. It is for a white linen counterpane. Linen embroidery in white thread is a considerable industry, well organised in the north-western part of Ireland.

FIG. 14.

INTERIOR OF A LONDON EMBROIDERY WORKROOM OF THE PRESENT TIME.

The next slide is of half of a painted design, and of the embroidery done from it, for a sideboard cloth, by a student of the Canterbury School of Art. The embroidery in this case is of coloured thread.

Of a more important grade is this panel of appliqué embroidery from the Plymouth School of Art, in which figures are introduced and a story-telling interest is given to the panel.

From the Glasgow School of Art is this design and its reproduction in embroidery. It is one of two or three panels illustrating the sands of Dee which were, I think, to be framed together as a fire screen.

Of another class altogether, and taking us back to the darning embroidery of the Egyp-

tians, Greeks, and Romans, are these specimens, which have been done quite recently under the supervision of Mrs. Christie, who gives instruction in it at the Royal College of Art. Two of them are pouches to hang from the belt and the third is a card-case.

A frame is shown containing an interesting example of a novel adaptation of darning to decorative figure design. The design and work are by Miss Keighley, of Plymouth School of Art. (Fig. 15.)

Fig. 15.

English Darning Embroidery of the Twentieth Century.

These different specimens serve to exemplify practice in embroidery as a branch of technical instruction in ornamental design, the provision for which is now considerable throughout the kingdom. In some places the arrangements for such instruction have been supplemented by organisations to help the successful students to carry on their work as a wage-earning industry, and commissions are given by private persons for the execution of special pieces of work, the designing of which involve expert skill. An interesting instance of work done under such circumstances is a mitre designed and embroidered in the convent of Poor Clares at the village of Kenmare in the south-west of County Kerry. This takes us back almost to a mediæval monastic condition of things, and I think that the nuns at Kenmare have shown much enterprise in organising their design rooms, and the employment of girls and women in the neighbourhood. Here, for instance, is a view of the Kenmare Convent design room. For the most part, as we see now, the designers are nuns; the embroidery is done partly by nuns and partly by girls under their direction. The specimen of their work which I now show is a bishop's mitre. It is of white satin; the ornament is adapted from devices found chiefly in Celtic filigree wirework on brooches, such especially as the famous Tara brooch which may have been made about the ninth century A.D., that is, at a time when Irish illuminators of MSS. were revered for their skill. Father Ultan is celebrated in a poem of that period, as a "blessed priest of the Scotic nation who could adorn little books with elegant designs. In this art no modern scribe could rival him, nor is it to be wondered at, if a worshipper of the Lord could do such things, since the Holy Spirit as an inspirer guides his fingers and raises his devout mind to the stars" The embroidery of the mitre is of coloured silks and gold threads. The second slide gives the back of the mitre, with the ends of the lappets embroidered with modern editions of ancient Irish ornaments.

I close my illustrations of modern English embroidery with two specimens of special design by Mr. F. Vigers: the embroidery is by Miss Symonds and her assistants.

The first is a casket or reliquary for use in connection with church ritual (Fig. 16.). The embroidery is of coloured silks and gold thread, in cross or tent-stitch on canvas, and furnishes the panels on the outside of the casket, which represents heaven as a building, with an open arcade and golden gate, and grill between the columns, within which are all sorts and conditions of men. St. Peter is at the gate, about to open it to a mortal who seeks admission: naked as he came into and left the world. In the upper arcade on the lid are angels rejoicing over the repentance of man. The colours in the original are brilliant and harmonious—the uniformity of stitch results in pleasant uniformity of texture—but the kind of stitch involves angularities, which are not quite agreeable in the rendering of curved shapes, as for instance in the arches, where slight distortions occur. On the other hand, the completeness of the work, the

brightness and sparkle of colour, the epical interest of the design outweigh the drawbacks which I mention. The casket seems to me to be a fresh, attractive, and individual embroidery.

My last slide is from the embroidered velvet train which was worn by H.M. Queen Alexandra on the occasion of the King's Coronation in 1902. This too was designed by Mr. Vigers. It was embroidered by many of Miss Symonds's pupils, who, amongst others, took part in the work. The scheme of design, with its symmetrically massed ornament, inclosed in borders, is obviously well suited to the shape and purpose of a train: the formality of the design is simple, but none the less accords

FIG. 16.

CASKET OF ENGLISH CROSS STITCH EMBROIDERY. TWENTIETH CENTURY.

with the spirit of the ceremony of state for which it was made. The balanced scrolling stems rising from the ancient form of Plantagenet Crown typify a growing rose tree as an emblem of England, on to which become engrafted the thistle of Scotland, and the shamrock of Ireland. These scrolling stems spread upwards, encircle the star of India, and culminate in the modern Imperial Crown which is repeated several times with sound, enriching effect over the main ground of the velvet train. Below the Plantagenet Crown the roots of the English tree are seen to be set amongst fleurs-de-lys — a reminder of the country's early connection with France. Thus a good deal of pleasant fancy underlies the ingenuity of ornamental design. The embroidery is principally of gold thread: the centres of the Tudor roses are silver: the floral parts of the thistles are picked out in purple silk, and the leaves have a touch of green. The technical difficulties to secure evenness in workmanship with comparatively stiff materials must have been considerable, but they were surmounted, and as we see in a way worthy of the traditional skill displayed in "opus Anglicum."

I have attempted in my lecture this evening to carry further the suggestion contained in my first lecture, that embroidery to be good and interesting, must be based on well-considered and well-expressed design. With primitive people, and others who follow traditional conventions, Chinese, Indians, and Mohammedans, for instance, the design and execution of single pieces are generally due to one person; but, I think, the results on the whole, are monotonous to western eyes, and have a strong impress of an *air de famille*, with little, if any, expression of individuality. On the other hand, in Europe, the designer has, as a rule, been a different person from the embroiderer. To achieve success, the two have co-operated; the designer paying due respect to the conditions and limitations of material and method, the embroiderer paying due respect to the form and colour which he is set to reproduce. English work of the thirteenth and fourteenth centuries seems to show that this was the case. Eccentricities of design in Elizabethan and Stuart embroideries point to a different condition perhaps. The embroiderers seem to have worked independently and without matured and carefully-prepared designs. Afterwards, say from early in the eighteenth century and up to within the last fifty years, designs for embroidery appear to have been made chiefly on the lines of mechanically repeating patterns, and the results have been comparatively uninteresting, tame, and not even amusing in eccentricity. No doubt we are now in the midst of a condition of things the tendency and effect of which cannot be summed up and thoroughly described. In some respects they seem to make for a good deal of vapid and tawdry display, quickly seen and quickly tired of; in other respects they seem to make for stimulating and thorough work, which is worth having and keeping, because, in making us look at it and think about it, it interests and refreshes us.

I thank you very much for the patient attention you have given to my remarks. I am sure that you will agree with me that the specimens lent by the Board of Education from the Victoria and Albert Museum have been of great interest, and have much increased the value of the other illustrations.

TRADE MARKS IN GERMANY.

It is curious to find that the Germans continue the practice of marking goods manufactured in Germany with British names and phrases so as to misguide the buying public. German industry is aiming in many directions to free itself from foreign dependence, to become as national as possible, but the preference for foreign commodities and foreign fashions has still to be reckoned with. All trade marks and names granted in Germany in the course of each month appear in the monthly issue of the *Waarenzeichen Blatt*, an official publication issued by the German Patent Office. In two recent issues alone 42 British marks and designs were directly applied for by Germans (exclusive of British marks applied for by British subjects through a German patent agent). Among such names and phrases were, *e.g.*, "The Greater Britain," and "The Cape to Cairo" as names for brushes; "Lord Kitchener" and "Lord Curzon" as names of knives, scissors, &c.; "Balmoral" as a name for earthenware; "Queen" as a name for razors, &c. Mr. Consul-General Oppenheimer (No. 3445, Annual Series) classifies the cases under three headings. The first class includes cases in which British denominations have become something in the form of technical words, *e.g.*, "linoleum," "inlaid linoleum," "buckskin," "Manchester," "waterproof," "Albert biscuits," &c. In some of these cases there is a tendency to replace the technical names by German ones, which are then enclosed in brackets, so that the present time marks a period of transition.

Between this class of manufacture and those who may be suspected of an attempted deception of the public at home and abroad is a second class, namely, those who, while not directly aiming at deception, appear to hope for it, for some combine with the English technical word another English word for which there appears no German equivalent, and which, in a way, has been received in the German vocabulary, *e.g.*, "sport razors" and "all-right bicycles." Others, again, copy the packing of the better-known British commodity as closely as possible, though introducing the name of their own firm, *e.g.*, biscuit tins. Others again, while avoiding the British trade names of wide reputation, concoct a name resembling the British one as near as the law will allow, *e.g.*, "Yvette cream" instead of "Everett cream," Saponia instead of Sapolio, &c.

As to the third class, who use purely English phrases to describe their German goods, Mr. Oppenheim points out that a difference ought to be drawn between those branches of manufactures in which it is said to be merely a custom of trade to use British names or words, and those branches in which no such custom can be pleaded in mitigation of the practice. Concerning the former, the practice of giving to articles of male attire British names is so general, that the shops selling these goods themselves go by British names, such as "Jockey Club," "Old England," the "Prince of Wales," &c. Concerning the latter, it can only be said that their goods bear British names and phrases when German ones ought to be used pure and simple. An important item in their mode of procedure is the trade-mark, the design of which is, as a rule, so devised as to deceive even those who examine it closely. The design, moreover, often bears at the bottom, the words, "trade-mark." Though this term may at one time have been a German technical word, it has long since been superseded by the German technical term "Schutzmarke," or "Waarazeichon." Among the articles thus sold are all kinds of perfumes, soaps, bay-rum, cosmetics, confectionery, jams, marmalades, canned provisions, biscuits, all kinds of paper and cardboard, &c.

FOREIGN TRADE OF JAPAN.

The annual return of the foreign trade of Japan for the year 1904, recently issued by the Department of Finance at Tokio, presents the statistics of the commerce of the country during the past year, as well as data showing the proportion of its trade with each of the foreign countries. Japan has certainly made rapid progress in her foreign commerce during the past ten years, and her trade with the United Kingdom and the United States shows a particularly rapid growth. The imports into Japan in 1904 were the largest on record, being £36,900,000 in value, as against £31,600,000 in 1903, £28,600,000 in 1900, and £13,300,000 in 1895. Exports from Japan in 1904 also established a new high record, being £31,800,000 in value, as against £28,800,000 in 1903, £19,800,000 in 1900, and £14,000,000 in 1895. Thus the imports into Japan have increased by £23,600,000, and the exports from Japan by £17,800,000. During the past ten years Japan has imported £40,000,000 more than she has exported, the excess of the imports over the exports averaging about £4,000,000 annually during that period. An examination of the statistical table showing the foreign trade of Japan by countries, indicates that Japan imports most largely from Great Britain, British India, the United States, China and Germany. These five countries supplying about 77 per cent. of her total imports. Of the total imports into Japan in 1904, amounting to £36,900,000, the United Kingdom contributed to the extent of £7,400,000, or 22·2 per cent.; British India (including Straits Settlements) £7,045,000 or 19 per cent.; the United States, £5,800,000 or 15·7 per cent.; China £5,430,000 or 14·8 per cent., and Germany £2,860,000 or 7·7 per cent. Of the exports from Japan, amounting to £31,800,000 in 1904, the principal countries of destination are the United States £10,080,000; China £6,770,000; France £3,610,000, Hong Kong £2,800,000; Korea £2,030,000; Great Britain £1,750,000, and Italy £1,200,000, these seven countries taking about nine-tenths of the exports

from Japan. It will be observed that the United States is by far Japan's best customer, exports to the United States from Japan representing about one-third of her total sales to foreign countries. The relative progress made by the United States and the United Kingdom in the import trade of Japan is seen in the following figures:—In 1884 the United States supplied 8·4 per cent. of Japan's imports, while the United Kingdom supplied 43 per cent.; in 1889 the United States supplied 9·3 per cent., the United Kingdom 39·4 per cent.; in 1894 the United States supplied 9·3 per cent., the United Kingdom 35·9 per cent.; in 1899 the United States supplied 17·3 per cent., the United Kingdom 20·3 per cent., and in 1904 the United States supplied 15·7 per cent. and the United Kingdom 20·2 per cent.

Since the revised Customs tariff came into operation in Japan in 1899, there has been a rapid increase in the Customs receipts, which rose from £881,000 in 1899 to £1,495,000 in 1904.

FLOWER FARMING IN AUSTRALIA.*

Although nature has become largely replaced by science in the manufacture of choice perfumes and essential oils, the demand for flowers for industrial purposes in various parts of the world is being steadily maintained, and in Europe and America flower farming is conducted on an extensive and remunerative scale. Yet in the countries of the Commonwealth, so rich in plants yielding delicious perfumes and valuable essential oils, little or nothing has been done, so far, to practically utilise the advantages thus afforded. Systematic flower farming is still in its experimental stages, and there exists an almost un-untouched field of illimitable extent at the command of those possessing the necessary capital and experience in the manufacture of perfumery and essential oils, coupled with the advantage of an abundance of mutton fat, so largely used in the perfumery trade, at minimum prices. In Australia all the garden flowers of Europe and Asia, especially those emitting the richest fragrance, are found growing in unsurpassed luxuriance, many being obtainable nearly all the year round, their profusion and cheapness proving how easily they are reared. Several of the essential oils obtained from the leaves of native plants are really perfumes, and their chief use is in scenting soaps and other preparations. The quantities used are small, most of the plants being wild. Among the native perfume-yielding plants which remain unutilised are several varieties of acacia, including a few which furnish a scented wood. The *Acacia farnesiana*, which is largely cultivated in Italy and the south of France—the well-known pomade, called "Cassia," being produced by placing the sweet scented flowers in melted mutton fat or olive oil, until the latter become impregnated with their odour—grows plentifully in many parts of New South Wales and other States; and another species of acacia, familiarly known as the golden wattle, is equally useful as a perfume plant; as is also the native laurel, or mock orange. Among the plants from which sweet-scented and other oils may be obtained are the native sassafras, peppermint, bloodwood, blue gum, mountain ash, white gum, ironbark, woolly butt, spotted gum, tallowwood, messmate, red gum, poplar box, and other species of eucalyptus; ridge myrtle, tea-tree, native peppermint, dogwood, and turmeric. The essential oil of the red gum has been found a reliable remedy for chronic dysentery and diarrhœa, and that of the Moreton Bay ash makes an excellent furniture polish. The oil obtained from the native sassafras resembles, in odour, ordinary sassafras oil, with an admixture of oil of caraways, and is used for medicinal purposes. Eucalyptus oil possesses many valuable qualities, and is said to possess the power of destroying bacteria, or animal life. Its antiseptic powers have been fully recognised by the medical profession, and by many it is preferred to carbolic acid in the treatment of wounds. The leaves of the various kinds of eucalyptus are found useful in preventing or removing scale in boilers. The oil of the mountain ash, a common species of eucalyptus, dissolves gutta percha readily, and can be used, like kerosene, for lamps, having a greater illuminating power, a pleasant odour, and absence of liability to explosion. Three ounces of the oil have been found sufficient to scent eight pounds of soap, at a cost of one farthing per pound. The oil obtained from the stringy bark is found to be more efficacious, in many complaints, than the ordinary English peppermint, being less pungent and more aromatic. The oil of the white gum has been suggested as a soap perfume. The woolly butt oil possesses the remarkable property of imparting an indelible stain to paper, but at present it has not been utilised for commercial or industrial purposes. The oil of the grey gum possesses a delicious citronelle odour, and makes an excellent soap perfume. Several varieties of the tea tree furnish an oil possessing most, if not all, of the properties of cajuput, so largely used in India as a remedy for rheumatism. Practically, the number of native shrubs and trees in the Commonwealth capable of being utilised in the manufacture of perfumes and essential oils is without limit, and when the large quantities of either product, obtainable from comparatively small proportions of bark or leaves, is taken into consideration, it will be seen that in this direction Australia posseses exceptional advantages for those possessing the requisite capital and experience to establish large and remunerative productive industries. It may also be mentioned that the olive, castor oil plant, and linseed grow luxuriantly in the Commonwealth, and are easily cultivated.

* Communicated by Mr. John Plummer, of Sydney, New South Wales.

HOME INDUSTRIES.

Motors and the Post Office.—Allusion was recently made in the *Journal* to the way in which the motor is affecting many industries, among them the carriage of letters. The report of the Postmaster-General on the working of the Post Office, just issued, shows that considerable extensions were during the past year made to the use of motor vans for the conveyance of mails, and that there has been a substantial advance in the reliability of the services already established. On some services the results have been, according to the official statement, "highly satisfactory," but on others the motor vans employed have not yet shown themselves so trustworthy as horse vans. It is, of course, imperative that vans used for mail services should work punctually and regularly, and it is necessary therefore to proceed with caution in extending the use of motor vans, and to exercise care in the selection of the contractors for the services. Motor services have been established between London and Epping, London and Redhill, London and Brighton, Manchester and Liverpool, Birmingham and Warwick, Birmingham and Worcester, Newcastle and Sunderland, and Northampton and Hitchin, and also between some of the London district offices. The employment of motor vans has in many cases resulted in an acceleration of the service, and where the loads are heavy and the distances considerable, in a substantial economy. Arrangements have also been made for the establishment of motor services between London and Hastings, with a branch from Tunbridge Wells to Eastbourne.

The Brewing Trade.—The Report of the Commissioners of Inland Revenue supplies some instructive figures bearing upon the brewing industry and the consumption of beer and spirits. The disappearance of small breweries is very noticeable, and is shown by the number of licenses, issued to brewers, for sale. In the year ended March, 1895, the number was 8,863, but since then there has been unbroken decrease until for the year ended March, 1905, the number of licenses issued was only 5,164. These figures relate to England only, but similar decreases are shown for Scotland and Ireland, the number of licenses issued throughout the United Kingdom having fallen, within the period named, from 9,050 to 5,311. The great decline in the practice of private brewing is illustrated by the figures which give the number of licenses issued to brewers, *not* for sale. In 1895 they numbered, for the United Kingdom, 17,041, in 1905 only 9,930, and the decrease is shown in all three kingdoms: in England, from 16,706 to 9,863; in Scotland, from 274 to 67; whilst in Ireland, the solitary one of the earlier year disappeared in 1900.

The Consumption of Beer.—If the figures showing the quantities of beer retained for consumption in the United Kingdom are taken, it will be found that there is shrinkage. The estimated consumption of beer per head of the population of the United Kingdom was highest in 1899-1900, when it rose to 32·28 gallons. Since then, there has been continuous decrease, until for 1904-5 it was only 28·44. It is, however, remarkable that the decrease has not extended to Ireland, if last year is excepted. Whilst in Scotland, as in England, the quantity of beer consumed shows steady decrease from 1899-1900, in Ireland, notwithstanding diminishing population, it continued to increase up to and including 1903-4. The figures below will make this plain:—

	England. Barrels.	Scotland. Barrels.	Ireland. Barrels.
1899-1900 ..	31,609,851 ..	1,931,295 ..	3,037,010
1903-1904 ..	29,705,535 ..	1,675,000 ..	3,358,102
1904-1905 ..	29,107,028 ..	1,596,715 ..	3,196,381

These figures are remarkable. They not only show that the shrinkage in consumption has been much less in Ireland than in England and Scotland, but that, having regard to population, and speaking roughly, the amount of beer retained for consumption in Ireland was about as much again as in Scotland.

The Consumption of Spirits.—The figures relating to the quantities of home made spirits retained in England, Scotland, and Ireland for consumption in the ten years ended 1904-5, point to a somewhat different conclusion. It may be convenient to give Tables as before. As with beer the high-level mark of consumption was reached in 1899-1900:—

	England. Proof galls.	Scotland. Proof galls.	Ireland. Proof galls.
1899-1900 ..	25,623,177 ..	8,380,378 ..	4,713,178
1903-1904 ..	22,974,805 ..	7,192,247 ..	3,936,059
1904-1905 ..	22,661,420 ..	6,758,901 ..	3,737,623

Here the decrease has not been unbroken, 1902-3 showing an increase in all three countries upon the previous year, but taking the five years there has been considerable decrease all round, the shrinkage in the Irish consumption of home-made spirits being somewhat more than in Scotland. Taking the ten years 1894-5 to 1904-5 the quantity of home-made spirits retained in the United Kingdom for consumption rose from 29,291,300 proof gallons in the earlier year to 33,157,944 gallons in 1904-5, being ·75 proof gallons per head of population in 1894-5 and ·77 in 1904-5. If instead of confining the return to home-made spirits, the consumption in the United Kingdom of all kinds of spirits, whether home made, colonial, or foreign is taken, 1899-90 retains its place as the year of greatest consumption, and there was a similar slight increase in 1902-3. In 1894-5 the quantity of spirits of all kinds consumed per head of population was ·95 gallons; in 1899-00 it had risen to 1·17, in 1904-5 it was only ·93.

American Grain Exports.—In the minority report of certain members of the Royal Commission on Supply of Food and Raw Material in Time of War—the minority report signed by the Duke of Sutherland, Mr. Chaplin, Mr. Wharton, Sir Henry Seton-

Carr, and Mr. H. H. S. Cunynghame—exception is taken to the prediction of the main report that the exports of wheat from the United States to Great Britain will diminish yearly. Far from being of this opinion, the gentlemen named consider that these exports "are far more likely to increase than to diminish, for a time at all events, and for this reason. In 1903 and 1904 the crops in the United States were deficient, especially in the latter year, whereas the estimate of this year's wheat crop, made by the statistician of the New York Produce Exchange, on the basis of official reports on the crop, is 728,000,000 bushels. If this estimate is accurate, it would indicate the largest crop on record, with the single exception of 1891, when it was 748,000,000. In 1904, the crop was only 552,000,000 bushels, and there is every reason to expect again an increased export from the United States larger than that amount."

Decrease in Exports.—Time only can verify or rebut this opinion of the dissentient Commissioners, but it may be pointed out that the latest official returns show no recovery in the exports of wheat from the United States. The explanation given by Mr. Consul Finn, in reporting on the trade and agriculture of the consular district of Chicago, under date March 16th last, deserves attention. "The wheat crop of the States," he writes, "has steadily decreased during the past four years, which can partly be accounted for by a decrease of acreage in this crop, but chiefly to the lessened yield from repeated crops on the same land, without any interval. The farmers who grow corn (maize) return the stalks to the ground as fertiliser, and alternate the crop with oats, besides often feeding cattle and hogs on the product, thus making a return to the land; but the wheat farmer in the United States goes on with the same crop year after year, returning nothing to the soil, until it no longer produces a paying crop. The land is then used for maize or oats, and under the new system becomes of value again. With the increasing home demand for wheat and the decreasing returns, more wheat will be grown profitably on land now used for maize, and grown in rotation with other crops . . . . In the older settled States in the East the farms are increasing in size, as dairying has shown itself to be more profitable there than raising crops, but in Illinois, Indiana, and Ohio small fruit and chicken farms have reduced the average acreage by a great deal."

The Home Supply of Wheat.—Be that as it may, the shrinkage in the home acreage under wheat continues. Whilst population and consumption increase the home production grows less. The total wheat crop of the United Kingdom at the present time amounts on an average to about 7,000,000 quarters. From this 15 to 20 per cent. must be deducted for grain unfit for milling or required for seed and other farming purposes. The quantity required for consumption in 1903-4 reached over 32,000,000 quarters, giving a *per capita* consumption of 364 lbs., showing an increase of 22 lbs. on that of the quinquennial period immediately preceding. The following figures show the shrinkage in the area of cultivation during the last fifteen years, as compared with the consumption :—

	1889-90. Qrs.	1899-1900. Qrs.	1903-4. Qrs.
Production	9,485,451	8,407,571	6,102,348
Average consumption per week ..	521,000	560,000	622,000

Of the 32,000,000 quarters of wheat required last year for home consumption, not more than 20 per cent. was of home growth. Probably the bottom point in home production has been reached. The demand for straw for various purposes must always operate to impede the decline in the production of wheat in this country, and the chief cause in the decline, the fall in price, has been checked, whilst probabilities point to some recovery in the immediate future.

Partnership Benefits.—Firms who would hold their own in these days of fierce competition, have to see to it that the per-centage of working expenses is as low as possible. Improved machinery, better means of distribution, and the like, tend to this desirable end, but community of interest as between employer and employed is less often invoked. And yet it may be made a potent factor in the creation or maintenance of business prosperity. Recently a very old established firm, whose relations with their workmen have always been excellent, found themselves confronted by competition that made it imperative to effect savings if the profits of the business were not to be seriously curtailed, and it was decided to adopt what may be called partnership benefits. Under the new arrangement each employee who has served the full twelve months receives one week's wage for every one per cent. earned and available for dividend over 6 per cent., that percentage being fixed as a fair return upon the capital invested. Those who have not served for the full twelve months, receive a bonus for 9, 6, and 3 months' service in like proportion. Interest on deposits of 20s., or over, is allowed as follows:—5 per cent. for deposits remaining for not less than 12 months, 4 per cent. for deposits remaining for six months, 3 per cent. for deposits remaining not less than three months. The whole or part of the deposit may be withdrawn on giving seven days clear notice. The scheme is said to work admirably. Now that they are to some extent partners in the business, the men take a keener interest in it, they are more careful to avoid waste of material, more eager to give the best of their work. The managers of the business are able to trace a distinct diminution in the cost of production to the better returns given by the workmen for the wages they receive, and the substantial addition to those wages consequent upon the adoption of the bonus scheme insures the maintenance of the happiest relations between employers and employed.

CORRESPONDENCE.

THE ETYMOLOGY OF "EMBROIDERY."

I am stirred to recast the etymology of "embroidery" in closer chronological and genealogical sequence than is followed in the first of his "Cantor lectures,"—[see *Journal* of the 11th inst]—by Mr. Alan S. Cole, C.B.

The word means, in its usage, the adorning of woven stuffs with needlework, in thread of a gold and silver, and variously dyed silk, flax, wool, and cotton; the "ars pingendi" [including the "ars plumaria," "featherwork"] of the Romans, and the *techne poikiltike* [compare "kilting"-work, and "kilt," the "tartan" or Tartareous petticoat, worn by the true Celtic Scots, but usually derived from *kilthe*, "the abdomen," the kilt ornaments rather than covers] of the Greeks, and the *rikhma* of the Semites of Anterior Asia [compare Arabic *rikama* "to write," to "broider"]:—also the broided work itself, the "opus picturatum," "pictura in textili facta," &c., of the Romans, and *poikilma*, and *poikilia* of the Greeks. The art undoubtedly had its origin in Chaldæa, and spread thence by way of Phrygia and Phœnicea into the countries of the Mediterranean sea, whence the Latin phrases "acus Babylonica," "opus Phrygium," &c.

As to the history of the evolution of the word, its oldest verbal forms are broder, and broider, and later embrouden and embroyden, and at last embroid, and embroider, the "er" in embroider being due to the substantival form of the word embroidery, and being as useless as the prefix "em," sometimes written "im," the equivalent of the French "en" and Latin "in." All these forms of the word are derived directly from the French *broider*, in its older form *broder*, and oldest, and only correct form, *border*, [as in *bordeur*], still preserved in the Spanish and Portuguese *bordar* "to broider," its incorrect forms being due to its confusion with "braid" [compare "broided (i.e. plaited) hair," 1 Timothy II.—9], a word of quite another history: and by all the rules of grammar the English verbal form should be [em]-border; and the substantival [em]-bordery; that is the ornamental needlework on the edge, welt, selvage, hem, border, "pretext," fringe, or "limbo" of textile fabrics,—where however the definition of embroidery overlaps lace and fringe, the work of the "limbolarii" of Plautus, in his Aularia, III., 473. But words, like as the flowers, are the daughters of Heaven [compare Sanskrit *vratam* literally "divine ordering," and Vach, the divine Cow, the mother of Speech], and as superior to grammar as was the Emperor Sigismund, and spring up, and live and die as they list:—and it is only Volopukes and Esperantots who imagine they can be artificially machinated.

GEORGE BIRDWOOD.

OBITUARY.

MISS MANNING. — Miss Elizabeth Adelaide Manning, who was the special guide and friend of young Indians who come to England to pursue their studies for the Bar and other professions, succumbed to an illness of some weeks' duration on the 10th inst. Born 77 years ago, she was the daughter of Judge James Manning, the last holder of the office of "Queen's Ancient Serjeant," who was well known in his time, and lived to be 84. Miss Manning was a member of the Society of long standing, having joined in 1875, a few years after she had relieved the celebrated Miss Mary Carpenter of a portion of her benevolent Indian work. Miss Carpenter died in 1877, but six years previously Miss Manning had become the Honorary Secretary of the National Indian Association, a position she continued until shortly before her death to fill with unfailing patience, judgment, and devotion. "Miss Manning's Association," as it has often been called, though much against her wishes, for she was very modest, is perhaps best known for its praiseworthy efforts to promote greater social intercourse between Europeans and Indians. It, however, grew out of Miss Carpenter's zeal for female education, and her successor always seemed to regard this as one of the most if not the most important of the aims of the National Indian Association. She herself contributed largely to its special education funds. In her earlier days she was Secretary of the Froebel Society and helped to establish Girton College, but for a generation India had practically absorbed all her energies. By two or three visits to the East she made herself acquainted at first hand with the educational needs of Indian women, and so highly were her unselfish labours appreciated by those who understood their value that she always could count on the assistance of leading Anglo-Indians. In June, 1904, the King-Emperor conferred upon her the Kaisar-i-Hind Medal, 1st Class, she being the third member of her sex to receive this distinction. The funeral took place on Monday last at Golder's Green Crematorium.

GENERAL NOTES.

MORTMAIN ACT.—In the fourteenth Annual Report of the Board of Trade recently issued under Section 29 of the Companies (Winding-up) Act, 1890, reference is made to an important point in connection with companies registered abroad. Express power is given to companies registered under the Companies Act (other than those not formed for profit) to hold lands in Mortmain, but this privilege does not extend to companies registered abroad, or in the

Colonies, or in Guernsey. Consequently none of these companies have power to hold land except under the authority of an express license from the King, and the Mortmain Act of 1888 provides that if any land is held by a company without a license, it shall be forfeited to His Majesty. The Comptroller of the Companies' Department says that this is an aspect of foreign registrations which has not been hitherto appreciated.

ADULTERATION OF RUBBER.—The director of the Para botanic gardens reports in the bulletin of the Para Museum that it has been recently discovered by a person unconnected with the production of rubber that a latex obtained from a tree, entirely different from the "Heveas," has been employed not only to adulterate rubber but in some cases to replace it altogether. Experienced estate owners, writes Mr. Consul Churchill, in referring to the subject in his report on the trade of Para (No. 3436, Annual Series), believe the substitute to be slightly less elastic than the genuine article. It seems that the great demand has led to the practice of adulteration for some years past. The trees in question are plentiful and exist over a very wide area. They are known in the State of Amazones by the name of "Tapurú," and in the neighbourhood of Para as "Murupita," "Seringa-Rana," &c. Botanists are of opinion that they belong to a species of "Sapuim." The word "Tapurú" is the Indian name for an insect, and is given to the trees because they are frequently destroyed by termites, particularly when tapping has been performed by unskilful hands. The advantages of the "Tapurú" and its congeners consist in their being more plentiful than the "Heveas," and in their more rapid reproduction.

BRITISH CEMENT EXPORTS.—Not many years ago San Francisco took nearly all its cement imports from the United Kingdom, now it takes none. To all intents and purposes it is a lost trade. The following figures give the British imports to San Francisco in the years named:—1902, 4,395,999 lbs.; 1903, 11,353,200 lbs.; 1904, 86,774 lbs. It was simply a question of time as to when imported cement would be entirely supplanted by the domestic article, and although Belgium and Germany still send a good deal of cement to San Francisco their exports last year were considerably less than half those of 1903. The great increase in public works, buildings, &c., in San Francisco has created an enormous demand for cement, but nearly the whole of it is supplied by local manufacturers. It is the same at San Diego. The total imports of 1904 amounted to only £7,704, showing a falling off of £24,064 as compared with the imports of 1903, and whilst £16,173 of the 1903 imports came from the United Kingdom in 1904 it sent none at all, Belgium and Germany supplying all that was imported. The cost of labour and setting up of cement plants has hitherto given the imported article a fair chance in the market, but as the local cement factories increase in efficiency, and permanently have the advantage of a short distance for distribution, the foreign product, more especially having regard to the preferential tariff, must expect to be shut out. California cement is packed in jute sacks which alone must effect a great saving in cost of delivery.

TRADE WITH ERZEROUM.—In his report, dated June 6, 1905 (No. 3442, Annual Series), Mr. Consul Shipley directs attention to the remarkable shrinkage of British exports to Erzeroum. British cotton goods showed a decrease of 25 per cent., as compared with the preceding year, and imports from the United Kingdom of all sorts a shrinkage of 20 per cent., German and Italian goods supplying the deficiency. Between them these two countries imported into Erzeroum for local sale or distribution in the neighbouring provinces, flannelette (called velour calico there) to the value of £100,000, £300,000 being the average total of manufactured goods imported there annually for sale or despatch inland. A few years ago these £300,000 were spent wholly in the United Kingdom. Now, "as a beginning," Germany and Italy have taken a third. It is high time, says Mr. Consul Shipley, that representatives of British firms should pay the district a visit and study the needs of the population. The difficulties of travelling are not so great as they are said to be; the Kurds are usually most hospitable to strangers, and the weather from May to October is generally fine. Mr. Shipley says he receives many trade catalogues in English that are not worth the postage spent on them.

JAPANESE COMPETITION IN CHINESE MARKETS. —The German Consul-General at Shanghai has recently addressed circular letters to German business houses in his district, advising the heads of the various firms to encourage the cultivation of a knowledge of the Chinese language in order to be able to meet Japanese competition, which, he says, after the close of the present war, will extend into western and northern China. The present system of selling goods through the agency of compradores will change, and ere long the trade will have to be carried on by the foreign houses direct. This will necessitate the *employés* of the various firms coming into personal intercourse with the Chinese purchasers, and for that reason a command of the language of the latter is requisite. In short, the Western nations must do as the Japanese do, if they do not want the latter to monopolise the trade. The Consul-General proposes a course of instruction for the German clerks and *employés* in the Chinese language, and offers to place his consulate at their disposal for this purpose, and the assistance of his interpreters. The German Consul-General's admonitions apply with equal force to British interests.

NOTICES.

SECTIONAL COMMITTEES.

APPLIED ART SECTION COMMITTEE.

The following is the list of the Applied Art Section Committee, as appointed by the Council:—

Sir Owen Roberts, M.A., D.C.L., F.S.A. (Chairman of the Council).
Sir George Birdwood, K.C.I.E., C.S.I., LL.D., M.D. (Chairman of the Committee).
Sir William Abney, K.C.B., D.C.L., D.Sc., F.R.S.
Thomas Armstrong, C.B.
George Frederick Bodley, R.A.
Prof. A. H. Church, M.A., F.R.S., F.C.S.
Alan S. Cole, C.B.
Sidney Colvin, M.A.
Walter Crane, R.W.S.
Henry Hardinge Cunynghame, C.B.
Cyril Davenport.
Lewis Foreman Day.
Alfred East, A.R.A.
Arthur Evans, F.R.S.
Hon. Sir Charles W. Fremantle, K.C.B.
J. Starkie Gardner, F.S.A.
William Gowland, F.S.A.
Gerald C. Horsley.
Thomas Graham Jackson, R.A.
Arthur Lasenby Liberty.
Seymour Lucas, R.A.
Sir Edward J. Poynter, Bart., P.R.A.
Sir Walter S. Prideaux.
Halsey Ralph Ricardo.
W. E. Riley.
Alexander Siemens.
A. B. Skinner, B.A., F.S.A.
R. Phené Spiers, F.S.A.
Hugh Stannus, F.R.I.B.A.
H. H. Statham, F.R.I.B.A.
Sir Joseph Wilson Swan, M.A., D.Sc., F.R.S.
Carmichael Thomas.
Sir John I. Thornycroft, LL.D., F.R.S.
Sir Thomas Wardle.
Sir Aston Webb, R.A., F.R.I.B.A., F.S.A.
Henry B. Wheatley, F.S.A. (Secretary).

CASTS.*

It is said of the late Walter Pater that the perfect copy of an ancient coin would give him as much pleasure as the original. To only the few is this power given of discriminating between the abstract and the extrinsic. The judgment of the majority is always largely influenced by accidental values such as antiquity and ownership can impart. If our insight is so clear that we can detach the intrinsic value from its surrounding glamour then a perfect copy will suffice for our edification. But it must be a perfect copy.

If we consider how such a copy can be obtained we shall soon see that no process of reproduction can be quite so perfect as that of casting. Neither can anything be quite so simple. A perfect impression of a coin, for instance, may be obtained in plaster of Paris, or, by the process of electrotyping in metal. The latter is only another form of casting, in which the metal is precipitated in the mould by electricity. While the electrotype is thus able to cast the object in the original medium, gold, silver, or copper, the plaster cast is no less perfect in reproducing the form, and, by departing from the original matter one is able to draw closer to the abstract beauty, to criticise more faithfully; the electrotype must always have some of the glamour of the antique coin itself. In speaking of casts, therefore, I shall take the cast in plaster of Paris as being the most satisfactory and appropriate form of the "perfect copy."

A plaster cast brings all kinds of objects to a common term, to use the language of mathematics; it translates bronze, marble, terra-cotta, ivory, &c., into plaster of Paris, the "universal language" of the plastic arts, we might call it.

Casting may be defined as the process of reproducing objects of three dimensions in three dimensions; a parallel case is offered by photography, which will faithfully reproduce two dimensions in two dimensions—giving "perfect copies" of manuscripts, drawings, &c. Photography will also reproduce three dimensions in two, of course, but that will no longer be a true representation or a parallel case.

A cast serves a double purpose; it often brings out the true value of the original, and multiplications of it enable comparisons to be made in any instance where comparison is necessary.

* Communicated by Mr. Max Judge.

To take the first case: whatever there is in an original object which is not transferred to the cast is parasitic; the original may be valuable for some romantic, perhaps fictitious, mutable reason; the cast is valuable as exhibiting the real value of the original. It will not reproduce ownership, antiquity, vicissitude.

The second case is merely an example of the value of multiplication, and concerns the applicability of casts, resulting from the expedient of obtaining an endless number of facsimiles of any one object.

Let us take the Venus of Milo in the Louvre as one example. A mould once taken, all the museums of the world are enabled to possess a perfect copy of the statue to help to complete their collections. They will have all that they require for intrinsic archæological reasons. There are, of course, extrinsic archæological data which can only be derived from the original, not because it is an original, but because it is the object that has been wrought upon by time and burial. The cast cannot reproduce the texture and the surface of the marble, but it reproduces the Greek conception. This statue, perhaps, is itself only a copy of the original. For a cast cannot alter the original conception of a thing. What is an "original"?—the perpetuation, in some form, of the idea of a master-mind. In the first instance it may have been evolved out of clay, to take its subsequent shape in marble or bronze; and the cast only takes the translation one step further.

The archæologist has not to depend on any one statue for the study of texture and *patina*. There are no collections which cannot include the beauty of the Venus of Milo; and for the form, the technique, the handling of the masses, a cast will serve the student as well as the Louvre original, *à seul* in its velvet-hung *Salon*.

Thus a cast means the facility of spreading abroad what would otherwise exist only in one place. What printing does for literature, photography for painting, casting does for the plastic arts; we should remember that printing is only the result of casting movable type.

We thus come to the employment of casts in the scientific study of archæology. In archæology, no less than in any other science, it is important to assimilate the existing data before any thought is given to projecting new theories and exploring new ground. Research is of no avail if that which has already been discovered is not commanded by the seeker after more truth. Until this is done it is useless trying to follow the results of the latest excavations or to criticise the latest "finds." The archæologist must know the famous collections, and by means of a comprehensive collection of casts he can know them without travelling through Europe from capital to capital. The catalogue of such a collection is the best manual of archæology that a student can study.

Without casts archæology as a science would have made much slower progress and settled into narrower channels. Think of the different statues of antiquity in the different corners of Europe. What *lacunæ*, what a want of relativity would exist in each separate collection if the gaps were not filled by casts! In the ideal collection there would be a strictly chronological order, exhibiting without break the gradual rise and decline of the various schools of the different countries. With casts at command of all, gaps cannot occur. One cannot lament the absence of any famous statue. We need not bemoan the fact that a certain example is in Paris. What does it matter where the original is in keeping—be it London, Paris, Berlin, Dresden, or Munich; as a cast it will fall into its place in this comprehensive collection, with a value unaffected by accidental locality, increasing the value of the collection by its inclusion in its fitting into, so complete a scheme.

If there is not the ideal collection here in mind there are several collections of great value from their comprehensive nature. Those at Berlin (New Museum) and Strassburg (University) come first in importance, and next must be placed the American collection in the Boston Museum of Fine Arts. The catalogue of this last collection is just such a manual as we have suggested as being the best help to the student.

Our own collection at South Kensington is not one that can compare with any of the three mentioned above. London should have its own comprehensive collection. The British Museum may be rich in original marbles, but they will not make up for the want of a distinct, complete collection wherein the comparative study of archæology may be pursued to the full.

Comparisons in archæology are never odious—rather are they essential. Only with casts can comparisons be effected with the fullest advantage. Different examples of the same type, slightly varying copies of a lost original, can thus be set side by side for analysis, and a more faithful synthesis of the original obtained.

In the Elgin marbles at the British Museum the frieze of the Parthenon is made more complete by casts of the sections in other collections and of those few blocks still *in situ* on the temple. Further, there are casts in duplicate of the same pieces, the second taken after an interval of several years, thus showing the result of leaving those precious panels to the mercy of time and weather—and showing too, ill-treatment which can be brought nearer home. The first set of casts, taken before subsequent disfigurement and decay, possesses, therefore, inestimable value; the casts, in fact, become original sources for study, seeing that they embody matter which is now lost in any other form.

In the Boston Museum already mentioned, there is another instance of a cast gaining additional value—becoming individual owing to its possessing some quality no longer the property of the original itself. The museum possesses one of the few casts of the celebrated Portland vase taken before it was shattered. The story of the broken vase is too well

known to need telling. The mould was taken while the vase was still the property of the Barberini family, and destroyed after a few copies had been taken from it in plaster of Paris.

There are other instances of casts having considerable interest and value attached to them—when they become more, in fact, than the "perfect copy" which we started with as the criterion. One is the cast at South Kensington of the Aphrodité of Cnidos. The statue itself, in the Vatican, has the legs and lower part of the body covered up with tin drapery to satisfy the peculiar prudery of the Italian authorities. No photograph has ever been taken of the statue "undraped," but fortunately the tin stuff was allowed to be removed, and a complete cast specially taken for our museum, and all photographs of the unadorned statue are from casts taken from that mould.

Another instance is connected with the famous copy of Myron's Discobolus, supposed to be in the Palazzo Lancellotti, at Rome—supposed to be, because there is very much uncertainty regarding it. The statue has been kept carefully "locked up," and there have even been rumours that it has gone to America. In any case it is not to be seen, and only one photograph of it has been taken. As it is agreed to be the most authentic copy of Myron's work handed down to us, it must be looked upon as a fortunate occurrence for archæologists when someone discovered in Paris a cast of the head of the statue, seeing that the statue itself is practically non-existent.

Curious instances of natural casting, or rather moulding, are to be seen at Pompeii, some of the results of the destruction of the city by Vesuvius. The objects of perishable material, buried in the lava, have decayed, leaving a vacuum, or in other words a mould, from which plaster casts have been obtained. By this resource even casts of human figures have been taken, by which we can judge of the accuracy of the results in other cases, where, for instance, a door has been thus taken in plaster and a reproduction then made in timber, with the original latches and bolts fitted to it. This is one of the most marvellous of the many marvellous secrets of antiquity drawn from Pompeii.

One more valuable application of casts must be noted, their use in connection with photographing the various objects which come into the hands of the archæologist. Photographs of coins and gems especially are always taken from casts, that is if the best results are desired. And in many other cases the cast brings out the *form* in the photograph better than the original would do. If, as we have said, the cast loses the surface and the texture, there is a certain recompense for this in the new light in which we see the form. That is a very interesting question. The perfect work of art may combine form and matter in such a subtle measure that until the matter is changed we may verily miss some of the gradations of the form. True, analysis undoes the unity of the art, but does it not show us a little more how great that art was—that art of Greece? In the unity of a masterpiece we are often unconscious of much which goes to make it what it is.

In conclusion, there is a danger connected with the practice of using casts which must not be overlooked. It is in connection with restored work. On the object itself the restorations are generally quite evident (or in some cases the little piece of the original can be detected) but as soon as the object is cast, unless special measures are taken to indicate the modern portions, the result is a homogeneous mass of plaster. It is of course very important to distinguish the old from the new, and if no such marks are desirable on the object itself, at least the name-label and catalogue should contain a careful statement of the restorations.

THREE SCIENTIFIC CENTENARIES.

In his Presidential Address delivered before the Mathematical and Physical Section of the British Association at Cape Town on the 17th inst., Professor A. R. Forsyth, F.R.S., specially directed attention to three interesting centenaries—1605, 1705, and 1805—

In this Section we are in the unusual position of being able to observe three scientific centenaries in one and the same year. Accordingly I propose to refer to these in turn, and to indicate a few of the events filling the intervals between them; but my outline can be of only the most summary character, for the scientific history is a history of three hundred years, and, if searching enough, it could include the tale of nearly all mathematical and astronomical and physical science.

1605.

It is exactly three hundred years since Bacon published "The Advancement of Learning." His discourse, alike in matter, in thought, in outlook, was in advance of its time, and it exercised no great influence for the years that immediately followed its appearance; yet that appearance is one of the chief events in the origins of modern natural science. Taking all knowledge to be his province, he surveys the whole of learning: he deals with the discredits that then could attach to it; he expounds both the dignity and the influence of its pursuit; and he analyses all learning, whether of things divine or of things human, into its ordered branches. He points out deficiencies and gaps; not a few of his recommendations of studies, at his day remaining untouched, have since become great branches of human thought and human inquiry. But what concerns us most here is his attitude towards natural philosophy, all the more remarkable because of the state of knowledge of that subject in his day, particularly in England. It is true that Gilbert had published his discovery of terrestrial magnetism some five years earlier, a discovery followed only too soon by his death; but that

was the single considerable English achievement in modern science down to Bacon's day.

In order to estimate the significance of Bacon's range of thought let me recite a few facts, as an indication of the extreme tenuity of progressive science in that year (1605). They belong to subsequent years, and may serve to show how restricted were the attainments of the period, and how limited were the means of advance. The telescope and the microscope had not yet been invented. The simple laws of planetary motion were not formulated, for Kepler had them only in the making. Logarithms were yet to be discovered by Napier, and to be calculated by Briggs. Descartes was a boy of nine, and Fermat a boy of only four, so that analytical geometry, the middle-life discovery of both of them, was not yet even a dream for either of them. The Italian mathematicians, of whom Cavalieri is the least forgotten, were developing Greek methods of quadrature by a transformed principle of indivisibles; but the infinitesimal calculus was not really in sight, for Newton and Liebnitz were yet unborn. Years were to elapse before, by the ecclesiastical tyranny over thought, Galileo was forced to make a verbal disavowal of his adhesion to the Copernican system of astronomy, of which he was still to be the protagonist in propounding any reasoned proof. Some mathematics could be had, cumbrous arithmetic and algebra, some geometry lumbering after Euclid, and a little trigonometry; but these were mainly the mathematics of the Renaissance, no very great advance upon the translated work of the Greek and the transmitted work of the Arabs. Even our old friend the binomial theorem, which now is supposed to be the possession of nearly every able schoolboy, remained unknown to professional mathematicians for more than half a century yet to come.

Nor is it merely on the negative side that the times seemed unpropitious for a new departure; the spirit of the age in the positive activities of thought and deed was not more sympathetic. Those were the days when the applications of astronomy had become astrology. Men sought for the elixir of life and pondered over the transmutation of baser metals into gold. Shakespeare not long before had produced his play "As You Like It," where the strange natural history of the toad which,

> "Ugly and venomous,
> Bears yet a precious jewel in his head,"

is made a metaphor to illustrate the sweetening uses of adversity. The stiffened Elizabethan laws against witchcraft were to be sternly administered for many a year to come. It was an age that was pulsating with life and illuminated by fancy, but the life was the life of strong action and the fancy was the fancy of ideal imagination; men did not lend themselves to sustained and abstract thought concerning the nature of the universe. When we contemplate the spirit that such a state of knowledge might foster towards scientific learning, and when we recall the world into which Bacon's treatise was launched, we can well be surprised at his far-reaching views, and we can marvel at his isolated wisdom.

I have implied that Bacon's discourse was in advance of its age, so far as England was concerned. Individuals could make their mark in isolated fashion. Thus Harvey, in his hospital work in London, discovered the circulation of the blood; Napier, away on his Scottish estates, invented logarithms; and Horrocks, in the seclusion of a Lancashire curacy, was the first to observe a transit of Venus. But for more than half a century the growth of physical science was mainly due to workers on the continent of Europe. Galileo was making discoveries in the mechanics of solids and fluids, and, specially, he was building on a firm foundation the fabric of the system of astronomy, hazarded nearly a century before by Copernicus; he still was to furnish, by bitter experience, one of the most striking examples in the history of the world that truth is stronger than dogma. Kepler was gradually elucidating the laws of planetary motion, of which such significant use was made later by Newton; and Descartes, by his creation of analytical geometry, was yet to effect such a constructive revolution in mathematics that he might not unfairly be called the founder of modern mathematics. In England the times were out of scientific joint: the political distractions of the Stuart troubles, and the narrow theological bitterness of the Commonwealth, made a poor atmosphere for the progress of scientific learning, which was confined almost to a faithful few. The fidelity of those few, however, had its reward; it was owing to their steady confidence and to their initiative that the Royal Society of London was founded in 1662 by Charles II. At that epoch, science (to quote the words of a picturesque historian) became the fashion of the day. Great Britain began to contribute at least her fitting share to the growing knowledge of Nature; and her scientific activity in the closing part of the seventeenth century was a realisation, wonderful and practical, of a part of Bacon's dream. Undoubtedly the most striking contribution made in that period is Newton's theory of gravitation, as expounded in his "Principia," published in 1687.

That century also saw the discovery of the fluxional calculus by Newton, and of the differential calculus by Leibnitz. These discoveries provided the material for one of the longest and most deadening controversies as to priority in all the long history of those tediously barren occupations; unfortunately they are dear to minds which cannot understand that a discovery should be used, developed, amplified, but should not be a cause of envy, quarrel, or controversy. Let me say, incidentally, that the controversy had a malign influence upon the study of mathematics as pursued in England.

Also, the undulatory theory of light found its first systematic, if incomplete, exposition in the work of Huyghens before the century was out. But Newton had an emission theory of his own, and so the undu-

latory theory of Huyghens found no favour in England, until rather more than a hundred years later the researches of Thomas Young established it on a firm foundation.

1705.

Having thus noted some part of the stir in scientific life which marked the late years of the seventeenth century, let me pass to the second of our centenaries: it belongs to the name of Edmond Halley. Quite independently of his achievement connected with the year 1705 to which I am about to refer, there are special reasons for honouring Halley's name in this Section at our meeting in South Africa. When a young man of twenty-one he left England for St. Helena, and there, in the years 1676-1678, he laid the foundations of stellar astronomy for the Southern Hemisphere; moreover, in the course of his work he there succeeded in securing the first complete observation of a transit of Mercury. After his return to England, the next few years of his life were spent in laying science under a special debt that can hardly be over-appreciated. He placed himself in personal relation with Newton, propounded to him questions and offered information; and it is now a commonplace statement that Halley's questions and suggestions caused Newton to write the "Principia." More than this, we know that Newton's great treatise saw the light only through Halley's persuasive insistence, through his unwearying diligence in saving Newton all cares and trouble and even pecuniary expense, and through his absolutely self-sacrificing devotion to what he made an unwavering duty at that epoch in his life. Again, he appears to have been the first organiser of a scientific expedition, as distinct from a journey of discovery, towards the Southern Seas; he sailed as far as the fifty-second degree of southern latitude, devised the principle of the sextant in the course of his voyaging, and, as a result of the voyage, he produced a general chart of the Atlantic Ocean, with special reference to the deviation of the compass. Original, touched with genius, cheery of soul, strenuous in thought, and generous by nature, he spent his life in a continuously productive devotion to astronomical science, from boyhood to a span of years far beyond that which satisfied the Psalmist's broodings. I have selected a characteristic incident in his scientific activity, one of the most brilliant (though it cannot be claimed as the most important) of his astronomical achievements; it strikes me as one of the most chivalrously bold acts of convinced science within my knowledge. It is only the story of a comet.

I have just explained, very briefly, Halley's share in the production of Newton's "Principia"; his close concern with it made him the Mahomet of the new dispensation of the astronomical universe, and he was prepared to view all its phenomena in the light of that dispensation. A comet had appeared in 1682—it was still the age when scientific men could think that, by a collision between the earth and a comet, "this most beautiful order of things would be entirely destroyed and reduced to its ancient chaos"; but this fear was taken as a "by-the-bye," which happily interfered with neither observations nor calculations. Observations had duly been made. The data were used to obtain the elements of the orbit, employing Newton's theory as a working hypothesis; and he expresses an incidental regret as to the intrinsic errors of assumed numerical elements, and of recorded observations. It then occurred to Halley to calculate similarly the elements of the comet which Kepler and others had seen in 1607, and of which records had been made; the Newtonian theory gave elements in close accord with those belonging to the comet calculated from the latest observations, though a new regret is expressed that the 1607 observations had not been made with more accuracy. On these results he committed himself (being then a man of forty-nine years of age) to a prophecy (which could not be checked for fifty-three years to come) that the comet would return about the end of the year 1758 or the beginnng of the next succeeding year; he was willing to leave his conclusion "to be discussed by the care of posterity, after the truth is found out by the event." But not completely content with this stage of his work, he obtained with difficulty a book by Apian, giving an account of a comet seen in 1531, and recording a number of observations. Halley, constant to his faith in the Newtonian hypothesis, used that hypothesis to calculate the elements of the orbit of the Apian comet; once more regretting the uncertainty of the data, and discounting a very grievous error committed by Apian himself, Halley concluded that the Apian comet of 1531, and the Kepler comet of 1607, and the observed comet of 1682 were one and the same. He confirmed his prediction as to the date of its return, and he concludes his argument with a blend of confidence and patriotism:—

"Wherefore if according to what we have already said it should return again about the year 1758, candid posterity will not refuse to acknowledge that this was first discovered by an Englishman."

Such was Halley's prediction published in the year 1705. The comet pursued its course, and it was next seen on Christmas Day, 1758. Candid posterity, so far from refusing to acknowledge that the discovery was made by an Englishman, has linked Halley's name with the comet, possibly for all time.

1805.

It is time for me to pass on to third of the centenaries, with which the present year can be associated. Not so fundamental for the initiation of modern science as was the year in which the "Advancement of Learning" was published, not so romantic in the progress of modern science as was the year in which Halley gave his prediction to the world, the year 1805 (turbulent as it was with the

strife of European politics) is marked by the silent voices of a couple of scientific records. In that year Laplace published the last progressive instalment of his great treatise on Celestial Mechanics, the portion that still remained for the future being solely of an historical character; the great number of astronomical phenomena which he had been able to explain by his mathematical presentation of the consequences of the Newtonian theory would, by themselves, have been sufficient to give confidence in the validity of that theory. In that year also Monge published his treatise, classical and still to be read by all students of the subject, "The Application of Algebra to Geometry"; it is the starting point of modern synthetic geometry, which has marched in ample development since his day. These are but landmarks in the history of mathematical science, one of them indicating the completed attainment of a tremendous task, the other of them initiating a new departure; both of them have their significance in the progress of their respective sciences.

When we contemplate the activity and the achievements of the century that has elapsed since the stages which have just been mentioned were attained in mathematical science, the amount, the variety, the progressive diligence, are little less than bewildering. It is not merely the vast development of all the sciences that calls for remark: no less striking is their detailed development. Each branch of science now has an enormous array of workers, a development rendered more easily possible by the growing increase in the number of professional posts; and through the influence of these workers and their labours there is an ever-increasing body of scientific facts. Yet an aggregate of facts is not an explanatory theory any more necessarily than a pile of carefully fashioned stones in a cathedral; and the genius of a Kepler and a Newton is just as absolutely needed to evolve the comprehending theory as the genius of great architects was needed for the Gothic cathedrals of France and of England. Not infrequently it is ifficult to make out what is the main line of progress in any one subject, let alone in a group of subjects; and though illumination comes from striking results that appeal, not merely to the professional workers, but also to unprofessional observers, this illumination is the exception rather than the rule. We can allow, and we should continue to allow, freedom of initiative in all directions. That freedom sometimes means isolation, and its undue exercise can lead to narrowness of view. In spite of the complex ramification of the sciences which it has fostered, it is a safer and a wiser spirit than that of uncongenial compulsion, which can be as dogmatic in matters scientific as it can be in matters theological. Owing to the varieties of mind, whether in individuals or in races, the progress of thought and the growth of knowledge are not ultimately governed by the wishes of any individual or the prejudices of any section of individuals. Here, a school of growing thought may be ignored; there, it may be denounced as of no importance; somewhere else, it may be politely persecuted out of possible existence. But the here, and the there, and the somewhere else do not make up the universe of human activity; and that school, like Galileo's earth in defiance of all dogmatic authority, still will move.

JAPANESE PAPER.

Japanese paper—by which is meant only paper made from the bark of plants indigenous to Japan, with a slight admixture, in certain cases, of other materials—being of a special character, is little exported. The export to China is the only one of any importance. In addition, a certain number of napkins, and thin copying papers, are exported to America, and an attempt to put notepaper on the foreign market has met with some success. In Japan itself, paper is used as a substitute for many articles, and foreign doctors there have largely adopted the use of thin papers for bandages. The striking point in the manufacture of Japanese paper is the absence of machinery. Everything is done by manual labour. Factories are almost unknown, the industry being carried on in a small way by each family separately. Except where the members of a family are insufficient there is no hired labour, and consequently paper-making families are less affected by the rise and fall in prices which follows the variation in the demand. Lately, one or two paper mills have been erected, notably in Osaka and Oji, a suburb of Tokio, but these are almost entirely engaged in making foreign paper. Such conditions are not conducive to progress, and until recently Japanese paper-making stood just where it was 500 years ago. Lately, however, much has been done to improve matters by the establishment of guilds. These look after the interests of their members and ensure them a market for their goods. At the same time, the guilds have teachers in their employ who point out to the paper-makers their mistakes. These guilds met with a good deal of opposition at first from the peasants, who did not always see the advantage of making good paper, instead of adulterating it with earth, and thus cheapening the cost of production.

In a report dated Tokio, May 1905 (No. 635, Miscellaneous Series), Mr. Oswald White, Student-Interpreter in the British Consular Service in Japan, gives an interesting account of Japanese paper-making. Japanese paper is made principally from the bark of three trees, the kozu or kaji (paper Mulberry, *Broussonetia papyrifera*); mitsumata (*Edgeworthia papyrifera*), and the gampi (*humanire Wickstrœmia Canescens*). Of these by far the most important are the first two, the latter being only used in making gampishi or koppi, copying paper. Formerly the amount of kozu used was far greater than that of mitsumata, but of late years the latter has been coming much more into use. The kozu is

grown in the fields generally between rows of mugi (wheat, barley) or of other plants, or along the borders. It needs a dry position fairly sheltered from the wind, which tears the bark, and open to the sun's rays. It is propagated by means of thin shoots from the root. These are taken off in November, buried in the ground in bundles, and planted out in April. By December the plant grows to a height of about 2½ feet, and is then cut down to within an inch of the ground. The following year there will be two or three stems, the next five or six, and so on. Every year it is cut down close to the ground in December. On an average a plant is good only for 15 or 16 years, as after that time the fibre becomes too tough. Owing to the fact that the harvest is in December, paper-making was formerly largely—and is still, to some extent—carried on by farmers as a temporary occupation in the winter when agriculture is impossible. The mitsumata is grown on the sloping ground in a position where it can receive a good supply of moisture. It must be sheltered to some extent from the sun, and altogether is a less hardy plant than the kozu. Propagation was formerly conducted as with kozu, but is now done by means of seed, which is much quicker. The seeds are sown in spring, 20 or 30 together. After a year the young plants are taken up and planted separately. Every year each stem puts forth three branches, thus giving rise to the name, viz, three forks—mitsu-mata. By the end of three or four years from planting the stem attains a thickness of about an inch, and is then cut down close to the ground. This takes place in April. Three, or, if necessary, four years are allowed to elapse before it is cut again; but after that the plant can be cut every year, though it is not used for more than about ten years altogether. The gampi is a bush growing wild on the mountains, and sought during the summer. Where possible it is pulled up by the roots. By this means several of the roots are broken off and left behind in the soil. These grow up again in three or four years. When the bush is too big to be pulled up it is cut down. Kishiu produces a great part of the supply of gampi.

The stems of the kozu and mitsumata from which the bark is to be removed are first cut into lengths of about 3 feet and then steamed for two or three hours. The top of the small furnace used has a cup-shaped cavity in the centre, containing water. Above this is placed a layer of two or three inches of straw, on which rests a barrel upside down containing the kozu or mitsumata. The object of the straw is to prevent any escape of the steam. After two or three hours steaming the bark becomes loosened and can be stripped off by the hand. The inner bark is then separated from the outer. In this operation the bark is first cleansed in water and the epidermis is then scraped off with a knife leaving the white inner bark. In the case of the kozu a good deal of the green part of the bark does not come off at first. This, when scraped off, forms the kasu used in chirigami. In the case of the gampi the bark separates naturally from the trunk without steaming. The epidermis and inner bark also separate naturally, but a good deal of the green part remains, which must be separated with a knife. The bark thus obtained is washed, dried, and then brought to market. Osaka forms the chief market for bark.

Japanese paper may be divided into the following classes:—(1) That made only from kozu; (2) from kozu or mitsumata, or from a mixture of the two; (3) from gampi; (4) from kasu, waste paper, &c. The only papers which are not now made from mitsumata as well as from kozu are those where great strength is necessary. One of the strongest of these papers is yoshino-gami (filter paper). It is also the thinnest—6,000 sheets when placed together only reach a height of about 13 inches. Its chief use is in filtering lacquer, several sheets being placed together for the purpose. As it does not tear the same paper may be used several times. Tengu-jo is a very similar paper, though slightly thicker and stronger. Like yoshino-gami, it is much used in felting. Another use is for pasting on glass windows with which shoji are sometimes made, a variety with designs being much employed. Japanese paper, being for the most part unsized, is of a very porous nature. The cement used mainly serves to bind the fibres together, and does not fill up the interstices as the sizing in foreign paper. This fits it very well, for the Japanese brush and ink which it absorbs. For the same reason it is impossible to write on proper Japanese paper with a pen. When a paper is required that can be written on with a pen, a sizing in which resin forms a principal part is used. Japanese paper is distinct from foreign paper in another way, its strength does not arise from any felting or intertwisting of the fibres, but from their length and tough nature. In papers of medium thickness the fibres lie in one direction only, while in thick papers the fibres lie in two directions at right angles. Thick paper is almost impossible to tear. Other paper, if made with a due regard to strength, will only tear in one direction, *i.e.*, parallel to the fibres. The strength of Japanese papers, not being assisted by any felting of the fibres, is not proof against wet, which dissolves the cement holding them together. The Japanese oil-paper, however, is excellently adapted for withstanding moisture. Another disadvantage of Japanese paper is that, owing to its porous nature, it is very liable to the attack of insects. But this may be guarded against by putting between the sheets certain leaves the smell of which the insects dislike.

In order to produce designs in the paper a silk gauze is used. The designs are drawn on paper, cut out and sewn on. The gauze is then laid on the scoop net, and the paper made in the usual way. The paper is thin in the parts corresponding to the designs on the gauze, thus reproducing them. Silk gauze without designs is also used in making the finest papers. To prevent the silk from rotting it

has to be dried every five or six days and painted with shibu (the astringent juice of the unripe kaki or persimmon). In Kochi, instead of silk gauze being used, the net is made of brass, and the designs sewn on it of copper. The objection to this method is that only thick paper can be made by it. The pile of newly-made paper is next pressed clear of liquid, and then the sheets are separated one by one, and spread out with a smooth brush on planks, which are dried in the sun. The sheets are then detached, and nothing remains to be done but to cut them to a uniform size. When, however, it is required to give a gloss to the paper one or two sheets are placed within thin plates of zinc and passed between rollers. As the sheets are dried in the open air the rainy season is the worst for the ordinary paper-maker. The pile may be left for a week or ten days without separating the sheets, but if left longer the colour of the paper changes. For this reason the few larger establishments have apparatus for drying the paper by steam where necessary. It is found that where paper is thus artificially dried the colour is not so good but the paper becomes stronger than if dried in the sun.

TRADE WITHIN THE EMPIRE.

The Annual Statement of the trade of the United Kingdom with foreign countries and British possessions in 1904, was issued last week. The figures relating to the trade between Great Britain, India, and the Colonies indicate expansion which in certain products has been large. One of the most striking evidences of this expansion is afforded by the fruit industry. Beginning with Canada, the import into the United Kingdom of raw apples has risen from 803,638 cwts., of the value of £427,763, in 1900, to 1,208,409 cwts., valued at £619,844, in 1904. The import of raw pears, and fruit preserved with or without sugar other than dried, also shows considerable increase. The increase in apples from Australia is comparatively much larger, although the total import is still only about a quarter of that from Canada. In 1900 87,748 cwts. of apples, valued at £113,445, came to the United Kingdom from Australia; in 1904 the weight had increased to 333,959 cwts., and the value to £336,781. Oranges, on the other hand, show a falling off from 1,519 cwts., valued at £1,460, to 996 cwts., of the value of £756 only. The figures for the West Indies show how rapidly the orange trade has developed in those islands. Below are the numbers imported in each of the last five years:—1900, 7,390 cwts.; 1901, 27,109 cwts.; 1902, 44,529 cwts.; 1903, 63,834 cwts.; 1904, 94,350 cwts. But the shrinkage in the banana trade is striking. The following figures give the number of bunches imported in each of the five years:—1900, 1,337; 1901, 547,043; 1902, 967,405; 1903, 682,883; 1904, 476,868. In 1904 the imports of bananas were less than half those of 1902.

Eminent authorities differ as to whether Canada is likely to very largely increase her corn exports to the United Kingdom. The land is there in abundance but some think the United States may soon take all Canada's surplus. Be that as it may the present growth of the Canadian exports of wheat to the United Kingdom is not very rapid as the following figures show:— 1900, 6,337,600 cwts.; 1903, 10,802,12[illegible] cwts.; 1904, 6,195,300 cwts. Wheatmeal and flour have increased from 1,195,219 cwts. in 1900 to 2,045,767 cwts. in 1904, but the imports last year were half a million cwts. less than in 1903, whilst the imports of barley, oats, rye, peas, and maize were very much less in 1904 than in 1900, maize dropping from 4,795,400 cwts. in 1900 to 1,872,700 in 1904. The wheat imports from Australia vary greatly. In 1900 they were 2,651,600 cwts., in 1903, owing to the drought, they had fallen to 26 cwts., in 1904 they reached 10,272,600 cwts. Wheatmeal and flour imports show similar variation. The meat imports have fallen away in a very remarkable way, if rabbits are excepted:—

	1900.	1902.	1904.
	cwts.	cwts.	cwts.
Beef (fresh)	413,991	65,860	76,345
Mutton (fresh)	446,049	270,134	163,014
Rabbits (dead	210,822	106,974	322,853

The meat imports from Canada are small if bacon is excepted, the import of which has increased from 529,864 cwts. in 1900 to 829,883 in 1904. Eggs have fallen from 807,702, "great hundreds," in 1900, to 317,722 in 1904, but cheese shows steady increase, from 1,511,872 cwts. in 1900 to 1,900,556 cwts. in 1904, and butter from 138,313 cwts. in the former year to 268,607 in the latter.

Perhaps the most remarkable figures in these food statistics are those which relate to the importation of wheat from British India. They are as follows:— 1900, 6,100 cwts.; 1901, 3,341,500 cwts.; 1902, 8,841 586 cwts.; 1903, 17,057,857 cwts.; 1904, 25,493,000 cwts.

The following figures give the value of the imports and exports from India and the leading colonies in 1900 and 1904:—

	Imports.		Exports.	
	1900.	1904.	1900.	1904.
	£	£	£	£
India	27,388,106	36,472,636	30,966,938	41,544,4[illegible]
Canada	21,764,021	22,621,164	7,605,257	10,024,221
Australia	23,800,820	23,568,918	21,575,828	17,336,47[illegible]
Cape of Good Hope	3,637,497	4,933,489	9,336,711	12,048,7[illegible]
West India Islands	1,670,206	1,895,212	1,771,860	2,024,3[illegible]

It will be seen that whilst the growth of our trade with India during the period under review was very large, with the greater colonies it has been more moderate, whilst the exports from Australia show a heavy shrinkage.

THE FUTURE OF THE CHINESE SILK TRADE.

The future of the silk trade of China merits the most careful consideration, not only of silk producers and manufacturers, but also of all those who are interested in the export and import trade, to and from, the Far East. Forty years ago, silk constituted 24 per cent. of the total exports of the Chinese Empire; in 1904 it represented 33 per cent., yet, in many resspects, the trade was unsatisfactory. In spite of favourable conditions abroad, Chinese silk, it is said, is beginning to lose its hold on the world's markets, but it is hardly likely that this will continue indefinitely, for with modern methods, China will again resume her old predominance in the silk trade. The silk production of China does not depend upon conditions and rules obtaining in other countries, and although, according to a recent report of the United States Consul at Amoy, many mistakes are being made in the methods of silk production, China can, and does, produce silk more cheaply and more extensively, counting its home consumption, than any other nation, by the sheer force of her position. The favourable climate and cheap labour make it possible for China to continue in the silk field, when, by every law of modern business, its ancient methods and continued bad management ought to have thrown it out of the struggle long ago. If China can continue to grow silk with bad management and without modern scientific methods, the world can surely appreciate the fact that, with the improved methods which are certain to come, even if they come slowly, which, in fact, are already being employed in some cases, will come such a volume of raw silk products as will give a new and permanent turn to the silk business of the world.

In China there is a vast population familiar with silkworm culture. A slight increase in the margin of profit to the producer will mean immensely increased production. Already the production is large. Ten of the eighteen provinces of China produce silk, although at present most of the Chinese silk is produced at Chekiang, Kiangsi, and Kwangtung. Take, for example, the Chekiang province, having a total area of 98,700 square miles; the total value of its annual production of cocoons is estimated by an expert at £500,000, or more than the total production of Fukushima, Shinshu, and Bushu provinces in Japan. At present, the best Chinese cocoons are the cheapest cocoons in the world, and yet, the Consul says, so far as the cost of labour and material is concerned, the cost of the production of silk may be further reduced and will indefinitely remain below the cost of production in Japan, not to mention America or Europe. As between the two nations in the Far East which produce silk, manufacturers should devote the closest attention to China. The silk industry of Japan is highly developed; it represents science and the most progressive business methods. The Japanese silkworm is not hatched unless the egg containing it has passed scientific examination. Nothing is left to chance. The mulberry leaves on which the worms feed, are grown upon trees scientifically cared for and protected from disease and pests. There is no loss in the growth of the trees, the hatching of the eggs, or the feeding of worms which do not produce. In China very much is left to chance, because the fathers of the present producers did not know any other methods than those now adopted. While the mulberry trees are cared for carefully in some cases, are fertilised and cultivated and stripped of their leaves in the autumn to give them a longer rest in the short winter, there is no protection for them from worms and other pests. The ravages of caterpillars and animal life generally are not prevented, while the average Chinese mulberry grove produces less than two-thirds of a crop of leaves as compared with other countries, and especially as compared with what is produced in China itself where the circumstances are more favourable. The treatment of the silkworms is of a similar character. The disease of the average silkworm stock in China is such that there is a constant and immense loss in worm food for which there is no return. It is estimated by a reliable authority that not more than 700 out of 1,000 eggs will develop worms to live through the several stages, and of these 700 not more than 400 will spin cocoons of any practical use, the other 300 having consumed food to no useful purpose. Such methods as are now employed in China in fact are cutting down the product of a mulberry tree fully one-half, and inasmuch as the groves themselves are more or less diseased there is further loss in this respect. With the acreage in mulberry groves now existing, and the trees and worms cared for on a scientific basis, the silk product of the Chinese Empire ought to be fully double what it is. Indeed it is difficult to appreciate the vast increase in silk production in China which will follow the introduction of scientific methods of culture. In spite of all this loss and these drawbacks, which would in time ruin the silk industry if not corrected, the first grade raw silk product of China is better than similar grades in Japan, and probably than in any other country. The Chinese silkworm naturally produces the largest quantity of the finest silk of any silkworm in any country. If the export of Chinese white silk has fallen off, as compared with that of Japan, it is due altogether to a failure to meet promptly the exigencies of the moment and to introduce modern scientific methods. The Chinese cocoon, especially cocoons from Chekiang and the northern provinces, is round or egg-shaped, bright in colour, with fine fibre, few joints, and a strong thread.

Some time ago an official of the Commercial and Agricultural Department of Tokyo, made a comparative investigation of the Japanese and Chinese cocoons and reported the following average quality of their production:—Japanese, good cocoons, 82·57 per cent.; double cocoons, 10·65; and waste cocoons, 6·78; total, 100. Chinese, good cocoons, 83·36; double cocoons, 8·62; waste cocoons, 2·90; cover cocoons, 5·12 per cent.; total, 100. It was

further shown that in length and quality of silk the Japanese cocoons are apparently superior to the Chinese, but in the fineness and uniformity of fibre the Chinese cocoons are superior to the Japanese. The test of strength was in the proportion of 59 for the Chinese and 45 for the Japanese fibre. In colour, in ease of manipulation, and in other respects, the Chinese cocoon leads. Having the advantage of a lower cost of production and natural superiority, Chinese silk production needs only the introduction of modern scientific methods in the culture and care of the mulberry trees, in the examination and sorting of silkworms' eggs, and in the care of the cocoons, to control the silk situation, not only in the Far East, but probably in the world at large. Chinese silk merchants still have an idea that they can, and do, fix silk prices for all markets. As a matter of fact, however, they can now do nothing of the kind. It is shown in the annual report for 1904 of the Chinese Imperial Maritime Customs, that "of the world's supply of silk, at present based upon the average of the past three years—1902 to 1904—and not including the home weaving of China and Japan, China provides 27 per cent. (North China 18 and South China 9), Japan 28 per cent., Italy 25 per cent., and all other countries 20 per cent." Yet if China produces 27 per cent. under present conditions, what it can and will produce under scientific treatment ought to be apparent to the silk world. It once took from 400 to 500 pounds of cocoons to make a picul (133 pounds) of silk. It now takes from 500 to 800 pounds. When the former figures are not only reached, but are bettered, China's real position in the silk industry of the world will be realised. The opinion of the Consul is, that because Chinese silk cocoons have been deteriorating on an average for some time, any expectation that the Chinese silk industry is disappearing or will disappear is a mistake. The silk business of the world is hardly in a position to do without one-third of its supply of raw material, hence pressure abroad will probably force the reform which the Chinese have been slow to make, but which, sooner or later, must come. At present raw material supplies must come from the cheap labour countries of the Far East—from China and Japan. For European and American manufacturers also it is to be considered that Japan is soon to be, if it is not already such, a competitor in the manufacture of those silk products which have heretofore been regarded as the peculiar product of European and American looms. In Japan the silk industry is commencing to change from an enterprise in which silk is produced from the mulberry tree and silkworm and incidentally manufactured into goods to an enterprise where raw materials from abroad are manufactured to suit the world's market. The importations of raw silk products from China into Japan are increasing yearly, and, with the passing of the war in which Japan is now engaged, it is only reasonable to assume that it will increase far more, marking what probably is a permanent change in the silk industry of Japan. This is to be the case not only because Japan is becoming more and more a manufacturing country, but also because Chinese raw silk is by nature better than Japanese raw silk, and can be produced more cheaply. It is not to be expected that there will be much, if any, change for the better in the silk situation of China until that change comes through action or demand from abroad.

There are several reasons for this, one of them being a lack of large amounts of ready capital and the unwillingness of Chinese people with sufficient capital to invest it at the present time. Another reason is, that while there are millions of people in China more or less well versed in the production of silk upon the present basis, there are very few who understand marketing their product, and these few are generally the middle-men, who are now making most of the money in the business. Probably the strongest deterrent factor, however, is the ever-baneful influence of monetary exchange, both international and that among the provinces and the several districts. The former two unfavourable elements could, and would be eliminated by foreigners doing business in China on behalf of foreign silk industries, and apparently there is no reason why much of the trouble from exchange could not be eliminated by a concern which is in business both in China and abroad. The Chinese themselves are paying considerable attention to the situation, and probably will invest more money in modern plants than they have ever invested before. One indication of this is in the increase in the number of factories for drying cocoons. If the price of silk continues as at present, if the silkworms are properly cared for, and if improved apparatus is imported, Chinese silk will, it is said, supplant all foreign raw silk, including Japanese, in the markets of the world. It is significant that, notwithstanding the fact that the price of silk has risen about 30 per cent. in the past few years, and apparatus for drying, steaming, and every other process has been greatly improved, the condition of Japanese factories is reported to be worse year by year. In Japan, this is attributed to two causes:—(1) Too many factories in proportion to the amount of cocoons produced, thus raising the price of materials by increased demand; (2) general rise in the cost of labour and everything, largely increasing the cost of production. The fact is that raw silk can be produced more cheaply elsewhere than in Japan, and the Japanese tariff is keeping out much of this material that the factories need. Already Chinese silk is finding its way into Japan, however, and the amount will increase as the price of Japanese silk for home consumption advances, and as Japanese silk manufacturers continue to go abroad for raw materials. The importation of wild cocoon silk by Japan during the past three years, may be regarded as a sign of the coming tide. There is now among Japanese manufacturers a growing appreciation of the importance of possessing factories in China for the purpose of controlling the business. If this, says the

Consul, is true of Japanese manufacturers, it certainly behoves European and American silk manufacturers to take action in the same direction. Europe and America will certainly continue to lead in the beauty and variety of their silk manufactures, but Asia will grow their raw materials.

EXPERIMENTAL COTTON PLANTING IN JAVA.

During 1903 a small quantity of prime Egyptian cotton seed was imported by the Mercantile Society of Amsterdam and planted on an estate situated on the high lands near Malang, East Java. On the advice of an authority on cotton cultivation, the seeds were planted, three grains per hole, at a distance of six inches apart. This distance, however, seemed to be too great. The soil was kept clean and free of weeds, and in a short time the seeds sprouted. When the plants began to bear leaves, they were transplanted. The plants developed well, and the average yield per plant may be considered very satisfactory, but when the crop was gathered in October, some eight or nine months after planting, it was found that 2,000 plants to the "bahoe" (1·75 acres) was not sufficient. The average yield was one picul (136 pounds) of clean cotton, and about two piculs (272 pounds) of seed to the "bahoe" (1·75 acres). On another estate near Malang, the yield has been somewhat better—204 pounds of clean cotton, and 408 pounds of seed to the "bahoe." The cotton has been cleaned by a patent hand machine with a capacity of from 4·2 to 5·5 pounds of clean cotton an hour. The quality of the cotton is as good as could be desired, the staple being fine and long, and shipments have already been made to the Netherlands. According to the American Consul at Batavia, the native cotton, "Kapasdjawa," is shipped almost exclusively to Eastern parts as raw cotton not cleaned from seeds. It has a very short staple, and is, therefore, unfit for weaving yarn, and its value is therefore slight. It is chiefly used for upholstering purposes. Under the most favourable circumstances it would never pay a European to cultivate this native cotton, the yield being valued at about £3 per acre per annum. The European planters therefore decided to experiment with other varieties, hoping that their efforts might in the end prove successful. In 1904 a further experiment was made in cotton, and although it has not yet been reported on, it is expected to be far more successful than the experiments in 1903. The soil has been well worked, and a more intensive mode of cultivation has been adopted than in the previous year. February is considered in Java the best time for sowing the seed, and October and November are generally the months for gathering the crop. The young plants have the benefit of the rain, and the crop is gathered before the next rains begin, which is absolutely necessary, as the buds are destroyed by heavy rains. In addition to the common hand gin used in 1903, a patent self-feeding double-action cotton gin has been ordered for working the 1904 crop. This gin can turn out forty pounds an hour, and is of one and a half horse-power. Some little trouble is experienced from caterpillars, especially in a wet season, but during the usual dry season, expected from the end of March to the latter part of October, there is not much difficulty in guarding against this pest, although this means constant watching. It has been ascertained that the cotton plants do not thrive well in a moist soil, and do not grow so well in virgin soil as in soil which has been planted for a season or more. It appears that the Netherlands Indian Government has, for a number of years, endeavoured to encourage the natives in different districts of Java in the cultivation of long-stapled cotton, but without success. Dr. Tromp de Haas, formerly connected with the botanical gardens of Buitenzorg, has written articles on the cultivation of cotton in Java in which he states that unfavourable weather and plagues are responsible for its want of success. Others, however, believe it is only a question of time when cotton will be successfully grown in Java. A firm of well-known spinners in Gronau has taken on trial a quantity of the Java cotton, and is quoted as reporting on it as follows:—"The Java cotton taken in hand is of splendid quality, and in colour especially is not to be distinguished from the Delta product. The staple is pretty equal, and the yarn may be used for numbers 40, 45, and, at the utmost, 50, and for exceptionally fine qualities. Planting this sort of cotton might prove remunerative. The samples sent have not been combed, though they look as if they had been." In addition to a few small trials made with imported Sea Island seed during the past year, experiments were to be made near Malang, and the following varieties were imported for planting:—Mit afifi, Abassi, and Yanovitch from Egypt; and Sea Island, Shine Upland, and King Upland from the United States. The first four are of long staple, and the last two of average staple. These were planted in a tract of about 70 acres, and the seed soon sprouted and produced healthy plants. When the first buds appeared the plants were in fine condition, and the most hopeful anticipations of good results were entertained if the rains would only cease. The rains, however, did not cease, and consequently what had been fine flourishing plants were stripped of their buds, and nothing but the bare stalks were left. Some plants attempted to bud again, but were attacked by small beetles, and in time they all died.

THE BRAZILIAN FIBRE INDUSTRY.

According to a recent report from Bahia, great progress has been made in the development of "caroa," the plant from which the natives obtain

the fibre employed in the construction of the ropes which bind the packages of tobacco sent to Bahia. Experiments were undertaken by an enterprising British syndicate in 1902, but good samples of sufficient bulk for ascertaining the commercial value of the fibre were only available for export in the autumn of 1903. These samples came from the Queimadas district; and although the machinery employed was rather primitive, excellent results were obtained. H.M. Consul at Bahia says it is certain that, with the experience already gained and the new and specially-constructed machinery, higher qualities of fibre will shortly be available and ropes produced which will rival the best Manilla. Experiments were commenced with sundry fibrous plants which abound in the whole district, but "carao" proving the most important and abundant, all other varieties were for the moment neglected. The natives extract the fibre by retting the long leaves for some fifteen or sixteen days, and then, fermentation having set in, the fibre is easily extracted. Another process employed is to break the ribbons with stones in order to remove the pectose or gummy matter. It is claimed that by these primitive methods a clever worker can obtain some ten pounds in a day. Much time is consumed in the operation of gathering the leaves—which usually measure from six to nine feet—owing to the strong, short thorns along their edges. Proper machinery obviates many of the difficulties of preparation, but it is not thought that any machine can be employed for the gathering of the leaf, owing to the dense nature of the bush. The crop is gathered by men who protect the palms of the hands with a strong pad of leather, a skilful man being able to pull one ton of leaves in five or six days. The breaking strain of some caroa ropes shown to the Consul was three tons to the square inch. For twine, the breaking strain was 135 lbs., and for yarn 200 lbs. to the square inch.

ADMIRALTY CHARTS.

The following is the official list of charts issued by the Hydrographic Department of the Admiralty in May and June last:—

New Charts.—No. 3497—England, east coast:—Hull road. 3498—Sweden, east coast:—Stockholm Skärgärd. 3501—Baltic; Gulf of Bothnia:—Approaches to Nystad (plans:—Fairway near Iso-Varestus. Anch. on W.C. of Lökö island). 3503—Germany, north coast:—Gulf of Danzig, western part. 92—Spain, south-west coast:—Cape St. Vincent to strait of Gibraltar. 2822—France, south coast:—Gulfs of Napoule and Juan, including Cannes and Antibes. 3496—Greece, west coast:—Scropha point to Cape Kamilafka. 3483—Black Sea:—Cape Lukul to Cape Meganom. 3502—West Indies; Puerto Rico:—Guanica harbour. 3495—West Indies, Leeward islands; Bieques or Crab island:—Port Mulas and approaches. 136—Bay of Bengal:—River Húgli—Saugor point to Calcutta. 3481—Bay of Bengal:—Moulmein river to Yé river. 3489—Bay of Bengal; Tenasserim:—Hinzé basin. 3504—Indian Ocean; Christmas island:—Flying Fish cove. 3440—Eastern archipelago:—Plans of anchorages between Celebes and New Guinea. 3487—Philippine islands; Luzon island:—Manila and Kavite anchorages. 3039—Arctic sea; Novaya Zemlya; plan added:—Lyamchina bay. 2221—Black Sea; plans of Russian ports on the north shore; new plan:—Mzuimta road. 3411—Africa, west coast; Garraway anchorage; plans added:—Rocktown Berebi anchorage; Grand Berebi anchorage; Sassandra anchorage; Port Bouet. 219—Malacca strait; Acheh head to Diamond point; plan added:—Lampujang strait. 2201—Sumatra; plans in; new plan:—Simalur island or Pulo Babi. 928—Borneo island; Sulu archipelago; new plan:—Maibun anchorage. 2196—Celebes; sketch plans of anchorages in southern part; plan added:—Bintaru anchorage. 3274—China; Yangtse kiang river:—Tungting lake and Siang river. Shanic Kan; Liu cha po; Chang sa. 836—Japan; Amakusa islands and Yatsushiro sea; plan added:—Kuro seto.

Charts that have received additions or corrections too large to be conveniently inserted by hand, and in most cases other than those referred to in the Admiralty Notices to Mariners:—

No. 3291—Germany; Elbe river, outer light vessel to Brunsbüttelkoog. 1479—Norway; the Naze to the North cape. 2306—Norway; Sheet IV.; Romsdals islands to Hitteren island. 3435—Plans on the east coast of Sweden. 2300—Baltic; gulf of Bothnia; Sheet V.:—Stiernö point to Fiäderäg, &c. 2247—Gulf of Finland; Hogland to Seskär, north shore. 798—France; west coast:—Douarnenez bay and approach. 1755—Spain; north coast:—San Ciprian bay to Cape Finisterre. 2235—Black Sea; Sheet IV.:—Fort Anakria to Kertch strait. 577—British Columbia; inner channels leading from Juan de Fuca strait to Haro strait. 395—Africa; west coast:—Isles do Los, &c. 1174—Africa; west coast:—Bonny, New Calabar, and Sombrero rivers. 641—Africa; south coast:—Port Elizabeth. 143—Red Sea:—Jebel Tier to Perim island. 901—Red Sea; Sawákin harbour. 1884—Bay of Bengal; Arakan river, Akyab. 2104—Eastern archipelago; Borneo island; Sheet I.:—South Natuna islands. 2987—Philippine islands; San Pedro to Libukan islands. 1742—China, Canton river; Sheet IV.:—Second bar pagoda to Whampoa, &c. 1739—China; Canton river; Sheet V.:—Whampoa channel and Chang shan island to Canton. 1601—China; north-east coast:—Wusung river. 61—Japan; Harbours and anchorages on the north-west coast of Nipon. 3109—Japan; Yokohama bay. 2294—Pacific; Sandwich islands:—Pearl river and lochs.

HOME INDUSTRIES.

Printers and Country Towns.—There is a growing tendency in certain trades to move from London to the country. This is particularly noticeable with the printing trade. Taking only towns within easy distance of the metropolis, it will be found that some of the largest London printing houses have branches at St. Alban's, Dunstable, Dorking, Redhill, Guildford, Reading, Swindon, Tonbridge. What may be called "rush" work must always, so far as it applies to London, be done in London, the time taken up in transit being fatal to country competition; but for all other kinds of work the small country town, well placed as to railway communication, offers many advantages. Rent is from 25 to 50 per cent. less, wages from 20 to 25 per cent. lower. The work is done in healthier surroundings, and there is less friction with the workmen, who are drawn from all parts of the country. Many—perhaps most—of them have London experience, but the managers of the works prefer countrymen to Londoners born, and have no difficulty in getting them. What the transference of a large printing business means to one of these small towns may be gathered from a single illustration. This one has a population of about 12,000, and until a few years ago its tradesmen had to cater only for the very moderate wants of a stagnant country town. Then two great printing firms set up works in the place, and now the wages bill of one of them is close upon £300 per week. Of this probably £250—or something like £13,000 a year—is spent in the town. And the money distributed in the form of wages by the other firm—an important one—must be large. It is, of course, only certain trades that have freedom of choice as to where they will have their works, but where there is such choice there is much in favour of the country site.

Rating of Machinery.—A League has recently been formed having for its object a clear definition of the existing law as regards the liability of machinery in the nature of personal property to be rated, or brought into account for rating purposes, with a view to establishing its exemption from such liability. In the final report of the Commissioners on Local Taxation (Cd. 638, 1901), reference was made to this question of the rating of machinery, and the Commissioners gave expression to the following emphatic opinion:—"It is beyond controversy that in any amendment to the existing law the main object to be arrived at must be the removal of all uncertainty as to what kinds of machinery are, and what are not, to be taken into account in estimating the rateable value of factories." The Commissioners recommended that "in estimating the rateable value of any hereditament occupied for trade, business, or manufacturing purposes there shall be excluded from the assessment any increased value arising from machines, tools, or appliances which are not fixed, or are only so fixed that they can be removed from their place without necessitating the removal of any part of the hereditament. But the value of any machinery, machine, or plant used in or on the hereditament for producing or transmitting such motive power, or for heating or lighting the hereditament shall be included." The present uncertainty as to the law, and the varying practice of rating authorities, are the chief points of complaint. In the City they only partially rate machinery. In Westminster they do not rate it at all. Elsewhere they are rating it at 10 per cent. of its capital value, which means, upon £1,000 of machinery, with rates at, say, 7s. in the £, an addition of from £30 to £40 per annum to the rates paid.

The Law as to Rating Machinery.—Up to the passing of the temporary Poor-rate Exemption Act of 1840, personal property which was local, visible, and productive, including stock-in-trade and all machinery whether physically made part of the manufactory in which it was found or not, was rateable according to the law. As a matter of fact, however, such machinery was not rated, though the practice in this respect varied in different localities. Stock-in-trade was still in law a subject of assessment, and to remove the grievance the Act of 1840 was passed. This Act, which has been kept in force by the Expiring Laws Continuance Acts, provided that "it shall not be lawful for the overseers of any parish, township, or village to tax any inhabitant thereof, as such inhabitant, in respect of his liability derived from the profits of stock-in-trade, or any other property for or towards the relief of the poor." Since the passing of the Act, machinery has not been rateable *per se*. On the other hand it has been decided that in valuing buildings (such as factories), certain kinds of machinery are to be taken into account in ascertaining the rateable value of the premises. What are the kinds of machinery that are to be taken into account in ascertaining the rateable value of a factory? According to Mathew, J. (now L. J.), whose language was adopted by the Court of Appeal, "the machinery ought to be taken into account as essentially necessary to the business to which the premises are devoted and manifestly intended to remain connected with the premises so long as they are used for the same purpose." Under the law as it now stands, as was pointed out by the Commissioners, the line between the kinds of machinery which are, and those which are not, to be taken into account in ascertaining the rateable value of a factory, is one that it is practically impossible to draw with any approach to distinctness. The result of this uncertainty as to what machines are, and are not to be taken into account in ascertaining the rateable value of the factory in which these machines stand is that a great divergence of practice exists among the rating authorities in different districts, and a large amount of dissatisfaction prevails among manufacturers in regard to the matter, "a matter," to quote the Commissioners, "that deeply affects the interests of some of the most important industries in the country."

Crops Without Stock.—The late Mr. Prout sought to solve the problem of feeding corn crops directly with suitable artificial fertilisers, and of cutting out the intermediary link of live stock as a means of manuring the land. This system of consecutive corn growing has now been carried out at the farm at Sawbridgeworth for forty years without a break, and in a letter to the present writer, Mr. W. A. Prout gives the result—"Wheat 35 bushels per acre, the average of the last 25 years. Under ordinary treatment the average for England is 28 bushels. From the year 1865 to 1879 the crops were sold standing, by auction, just before harvest, so during that period I cannot give you the yield per acre, as the purchasers never told me. Since 1880 the crops have been harvested in the usual way, and an annual sale of hay and straw held generally in April." As to the soil, Mr. Prout goes on to say, "The soil was analysed in 1865, 1877, and 1903, and the result was to show no exhaustion, but on the contrary it was richer in several ingredients in 1877 and 1903." It is not only with wheat that Mr. Prout's system has succeeded. Taking the years between 1880 and 1904, his wheat crops as stated have averaged 35 bushels per acre, his barley 39 bushels, and his oats 52 bushels. Adding the straw, which is also sold, the total returns from the three cereals have averaged, wheat £9 8s. 9d. per acre, barley £7 13s. 10d. per acre, oats £7 5s. 6d. per acre.

Cocoa.—The growth of the demand for cocoa in the United Kingdom in recent years has been remarkable. Taking the last fifteen years, it will be found that in 1890 the quantity of raw cocoa retained for home consumption was 20,225,349 lbs., in 1904 it had risen to 45,234,210 lbs.; and the total of cocoa or chocolate ground, prepared, or in any way manufactured, had increased from 2,141,786 lbs. to 10,052,247 lbs. Taking the quantities per head of the population the increase in the consumption of raw cocoa over the same period was from 0·54 lbs. to 1·06 lbs., and of preparation of cocoa and chocolate from 0·06 lbs. to 0·23 lbs. Trinidad continues to be in the forefront as a producer. The value of the island's export of cocoa increased from £500,000 in 1894, to £907,000 in 1902-3. The growth of cacao enabled Trinidad and Grenada to recover prosperity which had been lost by the fall in the price of sugar, but they will have to reckon with serious competition from other countries. Foreign Governments have recently sent experts to Trinidad to study the growth and preparation of cacao and the area of cultivation may be expected to increase rapidly. Already considerable quantities are exported from the Gold Coast and Egypt which possess a flavour preferred by the market for some purposes. The profit made by the cacao grower is very considerable, prices being well maintained, and the profit of the home retailer is also known to be large, so that there is plenty of room for competition to bring about a considerable fall in prices. The use of artificial drying is extending and its superiority to sun drying, both as regards quality and cost, appears to be demonstrated. Not much progress has been made in the study of the fermentation of cacao. Good results are now produced by purely empirical methods. The manuring of cacao trees has received some attention, and lime in various forms has been tried with beneficial results, but beyond this little has been done with artificial manures.

Colonial Exhibits at the Crystal Palace.—The exhibition of colonial products now open at the Crystal Palace can hardly fail to be of service to the Colonies and the United Kingdom, by making the public here better acquainted with the character of colonial exports. Not the least interesting section of the exhibition is that covered by the West India islands. As readers of the *Journal* know, many of the islands are turning to what used to be known as "mixed cultivation" to give them the profit they can no longer confidently reckon upon from the sugar plantations. Jamaica led the way with the export of bananas and oranges, and now other islands are following suit. None is better fitted by soil and climate to be a large exporter of fruit than Trinidad. The natural conditions there, including rainfall, all favour profitable banana growing, and Trinidad is not liable to hurricanes like the one that swept the standing crops to the ground in Jamaica in 1903. In many parts of Trinidad bananas thrive in a practically wild state, and the Royal Mail Steamship Company is about to make arrangements which will greatly facilitate the transport of the fruit to England. But there is a curious difficulty in the way of fruit culture for export in Trinidad. It is the large profit accruing from cocoa cultivation. Nothing pays like it, and from the big employer of labour to the time-expired coolie with his one acre of land, all cultivate cocoa wherever the land available is suitable for it.

Profits of Banana Growing.—Nevertheless the profits of banana growing are substantial. Some months ago, Mr. W. E. Smith, the general manager of the Trinidad Railway, was sent by the Agricultural Society of Trinidad to inquire into and report upon the methods of handling, transporting, and shipment of bananas and oranges in Jamaica, and in his report he gives some figures as to profits which are interesting. He took an estate of 300 acres, of cultivated cane land principally, which had been in cultivation about three years. The cost of clearing and preparing the land—ploughing, planting, weeding, and pruning—was a little over the average of £10 per acre. The initial expenses were fully realised with the first fruiting, after which the net clearance each year amounted to not less than £10 per acre. This is typical of many estates, both where irrigation is carried on and otherwise. An acre of bananas planted, say 14 ft. by 12 feet, will give roughly, 250 plants, or three stems to each stock. Under good tillage, and with average luck, these

should produce not less than 300 bunches annually, extending over the ratooning period, which varies from three to six years. To be on the safe side, take 260 full paying bunches, which realise an average price of 1s. 6d. The gross revenue comes to £19 10s., and after deducting say 45 per cent. for general management, including propping the fruit stems, reaping, carting, and interest on capital, the net clearance is not less than £10 per acre. One hundred acres of bananas in full bearing, under average conditions of soil, cultivation, and rainfall, would therefore mean an income of £1.000 a year. Mr. Smith, who is in charge of the Trinidad Section of the Exhibition at the Crystal Palace, says he should be inclined to say that these figures, which applied to last year, should now be reduced by 25 per cent. owing to the reduction in prices consequent upon the monopoly that has been established. But even if this reduction be made, a profit of £7 10s. per acre is a very handsome one.

CORRESPONDENCE.

THE NEW TRADE MARKS ACT.

The Trade Marks Act, which was passed last session and comes into operation next year, will make a new and most useful era in commercial legislation.

One of the first points which arrest attention is the sensible definition of a trade mark :—"It shall mean a mark used or proposed to be used upon or in connection with goods for the purpose of indicating that they are the goods of the proprietor of such trade mark by virtue of manufacture, selection, certification, dealing with, or offering for sale." Hitherto it was necessary to use a trade mark on the goods or on the bottle containing them. Under the new law it may be used in connection with goods—that is, by show-cards, posters on the hoardings, circulars, or by advertisements. Such pictorial embellishments are largely employed to attract public attention and to indicate various goods. The registered proprietor may be anyone practically who handles the goods. Hitherto trade marks have been held exclusively by manufacturers and merchants. Now the buyer who selects and the expert who certifies the goods may each register his brand.

The Comptroller-General of Patents, Designs and Trade Marks is appointed the Registrar of Trade Marks, and in any proceedings before him has power, with the consent of the parties, to require the attendance of witnesses, take evidence on oath, award costs, and be in the same position in all respects as an official referee of the Supreme Court.

What is a registrable trade mark has always been a vexed question and a fruitful source of litigation. Section 9 enlarges the scope of registration as follows :—

A registrable trade mark must contain or consist of at least one of the following essential particulars :—

(1) The name of a company, individual, or firm represented in a special or particular manner; (2) the signature of the applicant for registration, or some predecessor in his business; (3) an invented word or invented words; (4) a word or words having no direct reference to the character or quality of the goods, and not being, according to its ordinary signification, a geographical name or a surname; (5) any other distinctive mark, but a name, signature, or word or words, other than such as fall within the descriptions in the above paragraphs (1), (2), (3), and (4), shall not, except by order of the Board of Trade or the Court, be deemed a distinctive mark: provided always that any special or distinctive word or words, letter, numeral, or combination of letters or numerals used as a trade mark by the applicant or his predecessors in business before the 13th day of August, 1875, which has continued to be used (either in its original form or with additions or alterations not substantially affecting the identity of the same) down to the date of the application for registration shall be registrable as a trade mark under this Act. For the purposes of this section 'distinctive' shall mean adapted to distinguish the goods of the proprietor of the trade mark from those of other persons. In determining whether a trade mark is so adapted, the tribunal may, in the case of a trade mark in actual use, take into consideration the extent to which such user has rendered such trade mark in fact distinctive for the goods with respect to which it is registered or proposed to be registered."

A company will now, for the first time, be allowed to register its name if represented in a special or particular manner. This is an improvement on "particular and distinctive manner" in the present Act. The registration of the signature of the applicant's predecessor is also a useful innovation, as it enables a joint stock company to register its founder's signature as a new mark. Words having indirect reference to the character or quality of the goods will now be registered. This would appear to cover "Electric" velveteen ribbons, "Tower" tea, "Beatrice" shoes, and similar names which have been held not to be fancy words. Geographical names and surnames also, which have been excluded under the present law, will now be registrable, if their ordinary signification is not a geographical name or a surname. Hitherto many good trade marks have been refused registration because they were found among the names in the gazetteers and directories which include "Abbey," "Brook," "Palmer," "Silver," and "Golden," among thousands of common names.

Any other distinctive mark can be registered. This is very broad, as, under Section 3, a mark includes a device, brand, heading, label, ticket, name, signature, word, letter, numeral or any combination thereof.

The registration of associated trade marks is another important and useful provision. It enables an applicant to register the essential features of a label as

separate trade marks, and the user of the whole label shall be deemed to be a user of such separate trade marks.

A new feature is contained in Section 41, which enacts that registration shall, after seven years, be taken to be valid in all respects, unless obtained by fraud or calculated to deceive, or contrary to law and morality.

No proceedings to prevent infringement or recover damages in respect of an unregistered trade mark can be instituted, unless the mark was in use before August 13th, 1875, and has been refused registration under the new Act.

REGINALD W. BARKER.

Vulcan-house, 56, Ludgate-hill, London, E.C., August 22nd, 1905.

OBITUARY.

EARL OF ROMNEY.—Charles 4th Earl of Romney, who died on the 21st inst. at Gressenhall-house, East Dereham, the residence of his daughter, had been a member of the Society of Arts since 1880. He was great-great-grandson of Robert 2nd Lord Romney, the second President of the Society (1761-1794). The second Baron's sister married Jacob Viscount Folkestone, who was the first President of the Society (1755-61). Lord Romney was born on March 7th, 1841, educated at Eton and Christ Church, Oxford. He was J.P. and D.L. for Kent, and J.P. for Norfolk. He took a great interst in the mercantile marine and held the office of President of the Marine Society. Lord Romney was directly descended from Admiral Sir Cloudesley Shovell, whose eldest daughter and coheir married the first Baron Romney.

GENERAL NOTES.

BIRTHS, MARRIAGES, DEATHS.—The returns just issued show the births in England and Wales continue to grow less in proportion to population. For the second quarter in 1905 they were in the proportion of 27·8 annually per 1,000 of the population, the lowest birth-rate recorded in any second quarter since civil registration was established. The mean rate in the ten preceding second quarters was 29·4. In London the rate was 27·0, and, low as it is, it is higher than that of most continental capitals. There are no returns from Moscow or St. Petersburgh, but the annual rate per 1,000 in Hamburg was 26·2, in Berlin 23·3, in Amsterdam 26·0, in Antwerp 25·0, in Buda-Pesth 25·9, in Venice 23·2, in Brussels 19·5, in Paris 18·9 It was higher in Vienna, but only a fraction—27·6. And so with the death-rate, London compares favourably with other capitals, the annual rate per 1,000 being 14·3, as against 17·3 in Paris, 28·1 in St. Petersburgh, 32·0 in Moscow, 17 2 in Berlin, 20·9 in Vienna, 18·6 in New York. Moreover, if all the deaths of non-Londoners that occurred in hospitals and public institutions in London be excluded, the death-rate will not exceed 13·8 per 1,000. Taking the whole of England and Wales, the proportion is only 14·4, the mean rate of the ten preceding second quarters being 16·2. The figures hardly bear out the general opinion that life is much longer in the country than in towns. In 76 great towns, each with a population exceeding 50,000, the death-rate was 14·7 per 1,000; in 141 smaller towns, with populations ranging from 20.000 to 50,000, it was 13·6; in the remainder of the country, with an aggregate population of 13,750,000, of these more than 7,500,000 live in rural districts, the death-rate was 14·5.

MEAT AND FISH IN GERMANY.—What may be called the meat famine in Germany is likely to have a very appreciable effect upon the demand for fish, which fluctuates very largely in that country. In the winter months the consumption is considerable, but it falls off immediately after Easter, and remains small throughout the summer. There is at present, writes Mr. Vice-Consul Oliver, in his Report on German Sea Fishing, Trade, and Industry (No. 636, Miscellaneous Series) no question of fish becoming a staple article of food for the masses of the inland population, but active steps are being taken to popularise the use of it. In view, however, of the present high price of meat—and under the new German tariff which will come into force in 1906, the price of meat, the Vice-Consul thinks, may be appreciably higher—there is a strong probability that the consumption of fish will materially increase. The present duty on meat is:—For fresh and frozen meat, 15s. per cwt.; for salt meat, 17s. 6d. per cwt.; for smoked meat, £1 17s. 6d. per cwt.; and for lard, 9s. 9d. per cwt. Under the new tariff the duty will be £1 2s. 6d., £1 10s. 3d., and 15s. per cwt. respectively.

CURACOA.—Mr. Jacob Jasuram, His Britannic Majesty's Consul at Curaçoa, reporting on the trade and commerce of Curaçoa for 1904 (No. 3428, Annual Series) thinks that an "enterprising promoter might find it possible to form a company to build a dock, as the island's importance will be immeasurably increased"—as soon as the Isthmian Canal is built. Mr. Jasuram also thinks that anyone willing to establish electric, steam, or automobile tramway service, and fulfil Government requirements, will meet with no competitor "if arrangements can be entered into with the proprietor of the present line of tramcars, drawn by mules, who will be unable to retain the new concession if he fails to adapt the present antiquated service to steam, or to solve some other modern mode of conveyance."

NOTICES.

CANTOR LECTURES ON INTERNAL COMBUSTION ENGINES.

Mr. Dugald Clerk's Cantor Lectures on "Internal Combustion Engines" have been reprinted from the *Journal*, and the pamphlet (price one shilling) can be obtained on application to the Secretary, Society of Arts, John-street, Adelphi, London, W.C. A full list of the Cantor Lectures which have been published separately, and are still on sale, can be obtained on application to the Secretary.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

USES OF ELECTRICITY IN MINES.

By Henry Willock Ravenshaw,
Assoc.Mem.Inst.C.E., Mem.Fed.Inst M.E.

Lecture I.—Delivered May 15, 1905.

When your Council honoured me with an invitation to give a series of Cantor Lectures on the Uses of Electricity in Mines, I thought that I appreciated the extent of the task I was asked to undertake. I very soon found, however, that the subject is of such a wide character, that, to do ample justice in every direction, would require a great many more than the two lectures that I have undertaken to deliver.

In these lectures, therefore, I propose to confine myself within certain limits. On the one hand, I do not propose to go into the theory of the electrical transmission of power. The use of electricity is now so extensive, and the electric motor is so generally employed, that I feel safe in assuming that my audience has an elementary knowledge of the subject. On the other hand, time will not allow me to go very far into the mechanical side of the question.

Having set certain limits to my subject, I propose to describe as far as possible the various applications of electricity in general use in mines and to give you some data that have been obtained from actual practice.

I find that to the average Londoner, a coal mine is represented by a deep hole, at the bottom of which grimy men dig out the coal under dangerous and uncomfortable conditions, and that there is a general feeling of surprise when I describe the discipline and the wonderful machinery that is to be found underground.

Some idea, however, may be obtained of the magnitude of the work done, when I say that a large colliery may have an output of over 2,500 tons a day, representing six or seven of the immense coal trains that we constantly see on our main lines, and that in some cases, the whole of this coal is brought up one shaft 500 yards deep in 10 or 12 hours.

Taking an average thickness of seam of four feet, this represents an area of an acre and a-half of coal removed per week, or say 75 acres per annum. The result of so large an output is, that the distance from the shaft to the coal face (the place where the coal is actually obtained), becomes greater every year, and in many mines the coal has to be hauled, underground, at least a mile before it reaches the shaft.

To obtain these vast outputs, machinery has to be used wherever possible, and a large amount of power is required both underground and on the surface. Although power is sometimes produced in the mine by means of steam boilers and oil engines. it is usual to generate it on the surface and to carry it down the shaft by one of the following methods:—Steam is carried down in pipes; compressed air is carried down in pipes; continuous ropes are carried down from an engine on the surface; spear rods are alternately raised and lowered to pump water; electricity is carried down through insulated conductors.

To the average engineer the idea of a steam

pipe 400 yards long, is out of the question, yet, in a great many collieries there are pipes of that length carried down deep shafts to supply haulage engines. It is usual for steam to be turned on in these pipes night and day as the joints would be broken if the pipes were allowed to cool down. The loss from condensation is enormous.

Compressed Air is very largely used, and although the losses in the pipes are not so great as where steam is employed, the practical impossibility of warming the air before it reaches the engines, prevents a satisfactory economy from being obtained. Electrical transmission presents many advantages for this class of work, as the efficiency of transmission is high, the cables are easily carried down the shaft, and through roadways, and the motors have been brought to such a state of perfection that breakdowns are infrequent. It is, of course, understood that where there is electrical energy there is some chance of a spark being obtained that would ignite inflammable gas. Large numbers of motors are, however, in use in fiery collieries, and where adequate precautions are taken there is little or no danger. This is borne out by the fact that there are hardly any cases on record where a serious fire or an explosion has been traced to the use of electricity.

I propose to take each application of electrical driving separately, and to give you in some cases actual load curves that have been taken from the machines themselves. The following Table shows the various classes of machinery that are in general use, with the type of load and the range of sizes that are usually met with.

	Usual Sizes.	Type of Load.
Winding	50 to 2,000 B.H.P.	Intermittent with frequent short stops.
Single rope haulage	5 to 200 B.H.P.	Intermittent with long stops.
Continuous haulage	15 to 500 B.H.P.	Steady load.
Main and tail haulage	15 to 100 B.H.P.	Intermittent with fairly long stops
Locomotives	15 to 100 B.H.P.	Intermittent with variable stops.
Creepers	10 to 30 B.H.P.	Continuous variable load.
Coal cutters	20 to 50 B.H.P.	Intermittent with variable stops.
Pumping	5 to 500 B.H.P.	Steady load.
Air compressors	20 to 100 B.H.P.	Intermittent.
Fans	20 to 200 B.H.P.	Steady.
Screens	20 to 50 B.H.P.	Steady load.
Coal washing	20 to 100 B.H.P.	Fairly steady.
Stamps	15 to 100 B.H.P.	Steady.
Crushers	20 to 100 B.H.P.	Very variable.

Winding.—Steam-engines are at present almost universally used for winding, many of them being of large size, and capable of raising heavy loads at a high speed. The character of the load requires rapid acceleration and retardation with extreme accuracy of control. The importance of accurate control is shown in a diagram that I will presently explain, where an engine raises nearly 5 tons of coal in 42 seconds, from a depth of 541 yards. The load attains a speed of 45 miles an hour, and yet it only takes 12 seconds to bring it from full speed to rest. This is done 500 times a day all the year round with a remarkable freedom from accident.

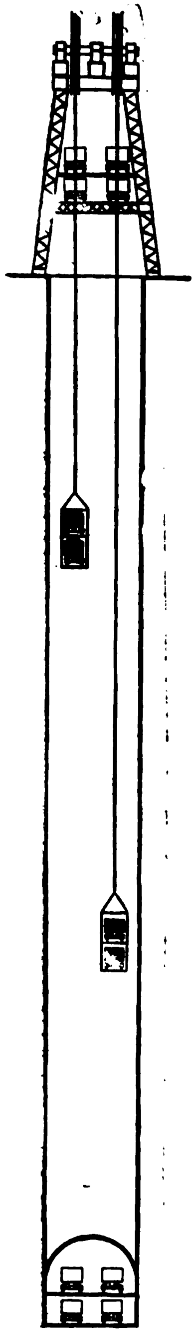
Some electrically driven winding engines of large size have been erected on the Continent, and are giving satisfaction; a good many are also being erected in this country. For small pits and staples (shafts connecting one underground level with another) electrical winding engines have been in use for a good many years, and I know of one which was put down in 1891, and has been in use ever since. Owing to the large amount of power required, and the extreme variations of the demand, the large electrical winding engine presents one of the most difficult problems that the electrical engineer had to deal with.

The problem is that the engine has to start a heavy weight of say five tons, from rest, raise it 500 yards in forty seconds, stop for fifteen seconds, and repeat the operation in the reverse direction. This means that the engine must give an enormous starting effort, and develop from 1,500 to 2,000 horse-power for thirty seconds. It must also be capable of absorbing a large proportion of the energy that has been put into the load so as to enable an accurate stop to be made at the end of its travel. It must be remembered that the moving parts are of great weight, and move at a high velocity, thereby increasing the difficulties in acceleration and retardation. This subject has been discussed to some extent by the members of the Institute of Mining Engineers and other societies, but I do not think that any diagrams have been published showing the actual work done by really large engines.

Where rapid and economical winding is necessary, it is important that the load should be as uniform as possible and this requirement is not obtained when the cages are unbalanced.

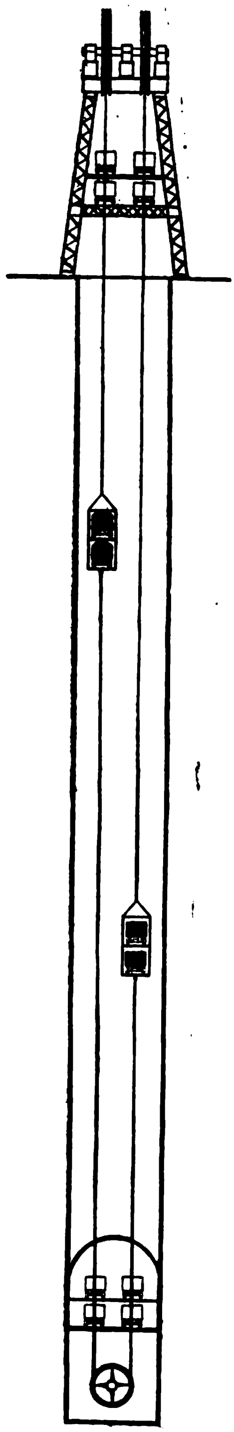
Fig. 1 shows the ordinary unbalanced system where the two cages are suspended from the same drum, one falling and the other rising. Owing to the great weight of the

FIG. 1.



ROPES UNBALANCED.

FIG. 2.



ROPES BALANCED.

rope the load on the engine is constantly varying; for instance, the unbalanced load at starting is the weight of coal to be raised plus the weight of rope. When the cages are passing the ropes balance each other, and the load unbalanced is equal to the coal being raised. Towards the end of the wind the weight of the descending rope predominates and actually overbalances the weight of coal. To give an instance in a particular case, the coal weighed three tons and the rope four tons. As a result the load against the engine at starting was seven tons, at the middle of the wind three tons, and at the end of the wind an overbalance of one ton was tending to drive the engine. This means an extremely variable load and a tendency to run away at the end of the wind.

A number of different methods have been employed for giving a better balance, and to illustrate my point I have shown on Fig. 2 a method which has many advantages, namely a balance rope. This, you will see, consists of a rope passing round a pulley at the bottom of the shaft and one end fastened to each cage. By this method the weight of the rope is balanced and the load is constant, namely, the coal to be raised.

By the use of a heavy balance rope the stresses due to inertia can also be partly balanced. This method of balancing is frequently used in this country, and it is doubtful if really fast winding can be economically carried out without this or some similar arrangement.

I have designed an apparatus for taking continuous records, and have shewn on Figs. 3 and 4 the result of tests taken from two large steam winding engines of modern design under actual working conditions. The engines are of very similar size, but in one case the weight of the ropes is balanced, and in the other it is unbalanced.

Fig. 3 shews that with the balanced arrangement a much higher rate of acceleration is obtained, steam is on the pistons for two-thirds of the running time, and the cages are very promptly brought to rest. In the unbalanced arrangement although the maximum horse-power developed per ton of coal raised is greater, the speed of wind is less, the acceleration and retardation are less rapid and steam is only applied to the pistons for one-half of the running time. It is an interesting fact that in neither case were the brakes used for retarding, and the large amount of energy required to stop should be noted. The peculiar shape of the power curve is due to the fact that in each case when the engine attained a speed of about 40 revolutions per minute an automatic cut off came into play. To illustrate the tremendous variations of load on the cylinders I would point out that in Fig. 3 steam was admitted during the whole of the stroke for six revolutions, it was cut off at one-fourth of the stroke for 14 revolutions, and the valves were reversed with steam against the load for five revolutions. The engine was moving again in the opposite direction in 12 seconds from the time it came to rest.

Although these diagrams do not bear directly on the question of electric driving, they are of the greatest importance as shewing the kind of load that must be dealt with if rapid winding has to be carried out electrically. It will be seen that to apply electrical driving to so variable a load presents considerable difficulties, and that if the demand on the supply is to be free from sudden fluctuations, some method must be adopted for storing up energy during the period of no load. Accumulators can of course be used, but the heavy first cost and upkeep are unfavourable to their general adoption. For small plants it is probable that a motor having the speed regulated between say a third and full speed by means of shunt resistance would give a simple solution, in conjunction with a motor carrying a heavy flywheel running free and connected across the mains. For large plants a more elaborate system has in some cases been adopted. The most characteristic of these is that adopted by Messrs. Siemens and Halske, and known as the Ilgner system. (Fig. 5.) This system includes a Ward Leonard motor transformer, consisting of a motor connected across the source of supply; this machine drives a very heavy flywheel and also a continuous current separately excited generator. The winding motor is also separately excited, and any speed can be obtained up to the maximum by varying the strength of fields of the two latter machines. This arrangement gives very accurate regulation, and has the advantage that the winding motor circuit need never be broken and that a considerable part of the energy given off during retardation is given back into the flywheel. The flywheel used in this system is very heavy, and running at a high speed, stores up a large amount of energy which can be given off as required by automatically causing the speed of the primary motor to be varied. A good many plants on this system are in

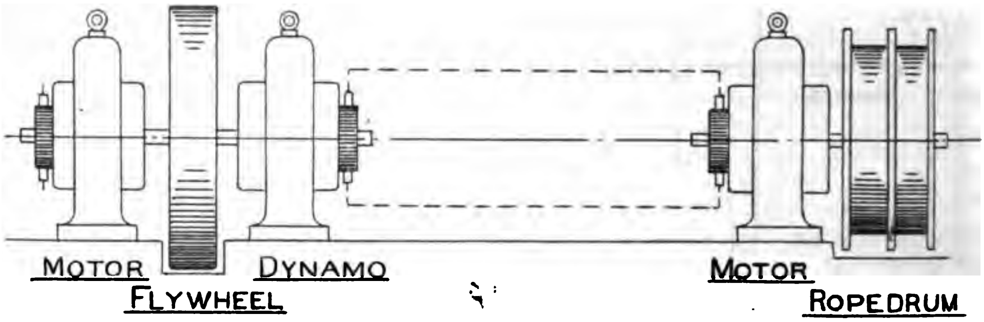
successful use on the Continent, and several are under construction in this country.

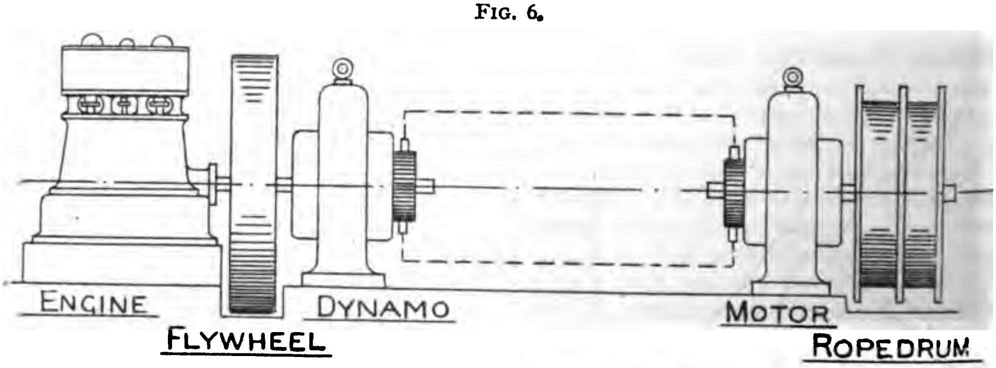
Heavy steel flywheels are used running at a very high peripheral speed, and the result of a burst wheel or a broken shaft might be extremely disastrous. It is of the utmost importance that they should not be placed in the winding engine room, and that they should be so arranged that, in case of accident, the damage would be localised.

FIG. 5.



Mr. Georgi has advocated a simple arrangement in which a high speed steam or gas engine is employed driving a heavy flywheel and a separately excited dynamo. The dynamo would be connected electrically to the separately excited winding motor, and the speed controlled as in the Ward Leonard arrangement. (Fig. 6.)

FIG. 6.



At first sight this appears to be a useless complication, but given highly efficient steam or gas engines there is a great deal to be said for the arrangement. With the advent of the steam turbine, and the still more economical gas engine producing electrical energy at a cheap rate, it is safe to prophecy that in the near future electrical winding will be very largely adopted. The following particulars of electrical winding plants, which are working in Germany, are of interest:—Zollern II. Colliery (Siemens and Halske Ilgner system).—Supply 520 volts direct current. Flywheel 12½ feet diameter; weight 45 tons; maximum peripheral speed 13,600 feet per minute; revolutions per minute 300 to 345. The motor generator takes 600 amperes to start, and after ten minutes takes 100 amperes light. When winding, the primary current varies between 250 and 450 amperes. Five tons of coal are raised per wind, the lift of 330 yards being made in forty-three seconds; the maximum speed is 1,980 feet per minute. The periods of rest are as long as forty-five seconds against twelve to fifteen seconds occupied in some of our best collieries.

At the Preussen II. Colliery there is a large winding engine driven by a three-phase motor. Pressure about 2,300 volts, 25 cycles per second. No arrangement is fitted for storing energy between the winds. Three tons of coal are raised per wind, the lift of 600 yards being made at an average speed of 1,800 feet per minute. The maximum speed is 3,200 feet per minute. This is a successful plant, but there have been difficulties owing to the low power

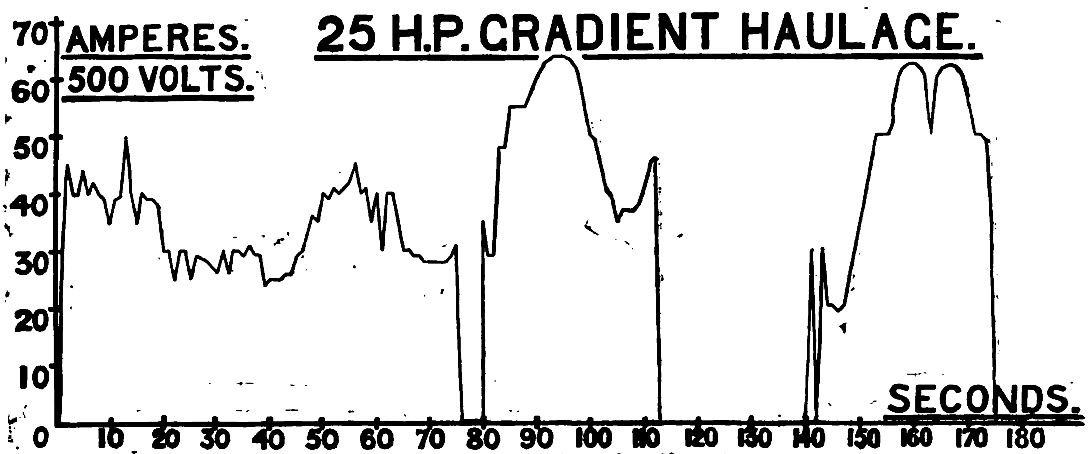
factor of the motor at starting causing great variations of supply pressure.

Underground Haulage. — Underground haulage comes next in importance to winding, as with modern developments of large collieries the coal has very often to be hauled underground for a distance of two or even three miles. In this country most of the coal seams lie on a slope, and consequently, although the coal that is obtained from the higher level will descend by gravity to the bottom of the shaft, the remainder has either to be brought along the level or up hill. Wire rope haulage is almost always employed.

Where the slope is not less than 1 in 20 the empty corves will descend taking the rope with them and either single or double roads are attached to each end of the train, and it can be hauled in either direction. In this case the motor does not usually reverse, two drums being fitted connected to the shaft by clutches. The motor generally starts with the load, and owing to the trains having to be hauled in both directions, the demand for current occurs twice as frequently as with the single rope haulage. Continuous rope haulage is very largely adopted and has many advantages. There are two roads, main and return, and the corves are either attached to the rope singly or in sets, the speed being about four miles per hour. The advantages of this system are regular supply, slow speed, and consequently fewer accidents.

The load on the motor is an excellent one,

Fig. 7.



employed. In the case of double road haulage the system is very similar to that adopted in winding, and the load is of the same character. With a single rope the motor runs in one direction, as, in lowering, the drum is let free, the empty corves unwinding the rope as they run down the incline. The load on the motor is consequently intermittent, the motor not being in use for more than half the time.

Fig. 7 shows a load curve taken from a 25 horse-power single rope haulage motor from which you will see that there were excessive variations of load owing to curves and steep places on the incline. This demand on the supply was repeated every half hour.

Where the roads are flat or undulating, main and tail haulage is frequently used, a second rope being carried on pulleys to the end of the roadway, round a large pulley, and back to the tail end of the train. There is therefore a rope as the demand is usually practically constant while the motor is running. Fig. 8 shows a record taken from a 25 horse-power single rope haulage plant, which is only intermittently used, there being 20 runs of about five minutes duration in eight hours. Where several roads are served, and separate ropes used for each road, all the rope pulleys are driven from one motor, and the demand is remarkably steady. I have frequently seen the ammeter connected to a 200 horse-power motor remain steady to within 5 per cent. for long periods. Some very large continuous haulage motors are at work in this country.

Electric Locomotives are very little used in this country, the only one with which I am acquainted being in the Greenside Mines, under Helvellyn, in Westmorland. In the United States they are largely used, the coal being more free from faults than in this

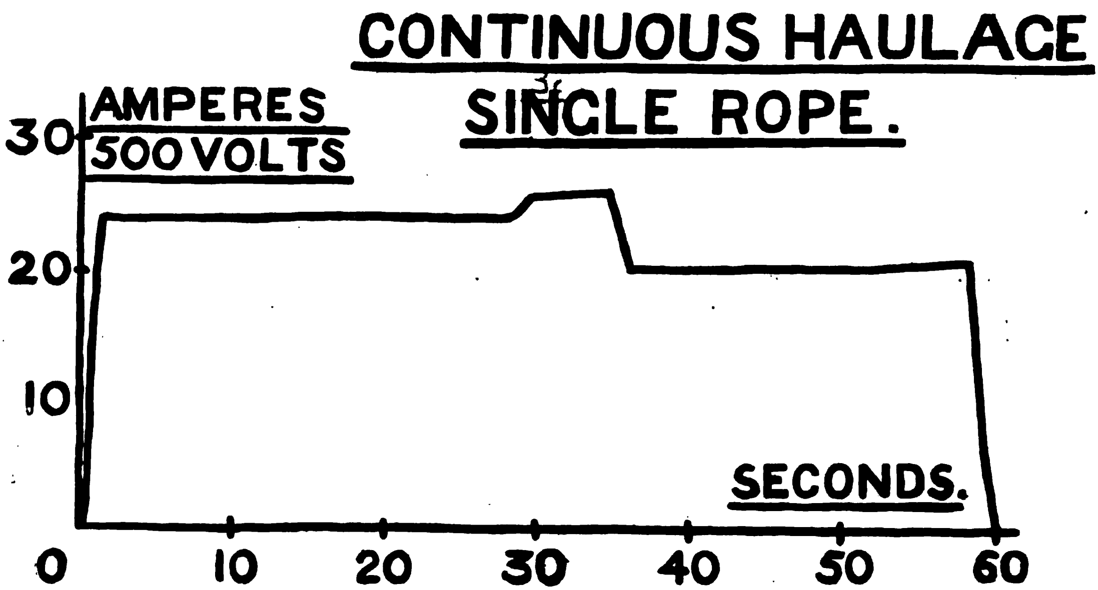
country, and the roads consequently more level. In many of their collieries the coal outcrops and the locomotives are able to bring trains out of the hillside without the intervention of a winding shaft. Electric locomotives are capable of working up an incline of one in twenty. A trolley wire or live rail cannot of course be used in fiery mines.

A Creeper is a form of conveyor to bring trucks from one level to another. They are frequently used at pit bottoms and on the surface. The load is somewhat intermittent, but the power required is small. Electrical transmission is extremely convenient for these small applications.

largely used. Dip pumps are mounted on a truck, and are moved down the falling roadway as the water is pumped out. Some very large pumps are in use on the Continent coupled direct to slow-speed motors.

Electrical driving is particularly applicable to centrifugal pumps, and it is on record that a pump of this kind is working against a head of 1,850 feet and raising 1,750 gallons per minute. A pump load is an extremely good one from the supply point of view, as the demand is practically steady. Electrical pumps are frequently placed in out of the way places, and receive attention perhaps twice a day. A very convenient and economical arrangement

Fig. 8.



Pumping.—This is a most important application. In some cases the weight of water raised exceeds the output of coal. The extreme flexibility of electrical transmission makes it particularly useful in the case of shaft sinking, and for following drifts and workings that are on a downward slope. In many cases very little power is required, as a very small pump will deal with 20 gallons a minute, but unless dealt with that flow of water will very soon flood out a large district. In one of the collieries with which I am connected, two pumps, absorbing together not more than 10 horse-power, have entirely cleared a flooded district, the water-level being reduced by 150 feet. The ordinary three-throw pump is a most useful type, and is very

can be obtained where the generating station supplies current for haulage during the day and for pumping at night. The capital expenditure is kept down in this way to a minimum.

Coal Cutting.—This is an extremely important application of power to mining, and a large number of electrically driven machines are at work. They can be divided into three classes, namely—disc, chain, and bar cutters. Special merits are claimed by the makers for each type of machine, the disc machine being most largely used in this country. The system of getting the coal known as long wall is generally employed where coal cutters are used, the machine usually making a horizontal cut from four to six feet deep underneath the

coal. As the cut proceeds the machine hauls itself along the face of the coal, being supported either on rails or on a sledge.

Series motors are generally used with direct currents. The Diamond Coal Cutter Company use two motors coupled in series. Multiphase motors are also successfully used for this work, but the great starting effort that a series motor will develop makes the continuous current machines more popular with the men, especially where deep holing can be carried out. The current is conveyed to coal cutter motors by means of long trailing cables well protected from injury, and arranged so that they can be readily disconnected.

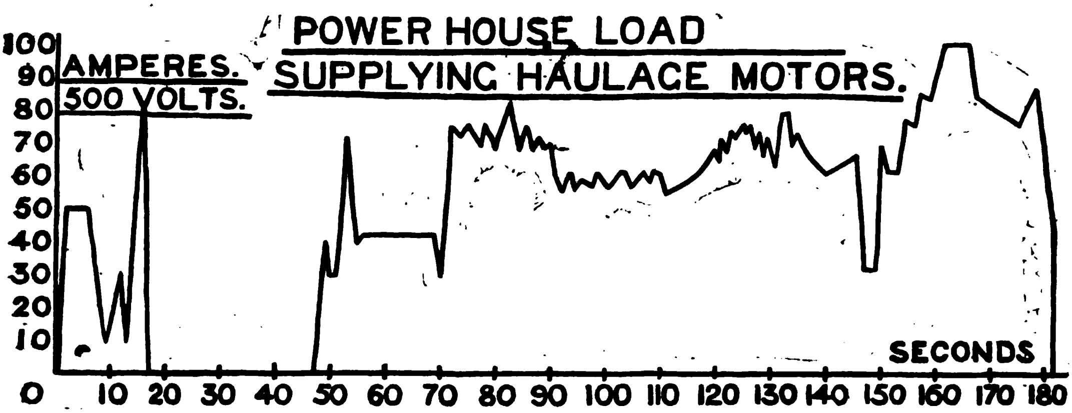
The main cables are generally brought to switch boxes in the gateways at several points along the face so that a long face can be worked without using cables of excessive length.

Electrically driven air compressors are being extensively used, and where rock drills are employed advantage is taken of the cheapness and flexibility of electrical transmission to drive the air compressors underground. Compressed air can be more safely used than electricity for coal cutting in very fiery mines, and electrically driven air compressors fixed some distance in-bye are also being used. There is good reason to believe that this combination of two methods of transmission is likely to be largely employed. There are numbers of other applications of electrical driving in mines, and it is interesting to note that a considerable discussion has been lately going on among engineers in the Rand as to the relative advantages of driving large numbers of stamps by one motor or dividing them into sections. It is likely that the latter system will survive, as the experience of engineers points directly to the great advantages to be obtained in sub-dividing the plant into sections of a reasonable size.

Generating Stations.—As I have already pointed out, the load on many classes of mining machinery is of a very variable character, and as a result, the demand on the generating stations is not always a satisfactory one.

In some cases where the haulage is continuous, and there is a good deal of pumping, a steady load is maintained for long periods; but to show that this is not always the case, I have a diagram (Fig. 9) showing readings which were taken for three minutes from a dynamo supplying three haulage engines varying in size from $7\frac{1}{2}$ to 25 horse-power.

FIG. 9.



You will see that at times there was no demand whatever. A dynamo running alongside and supplying screens and washing plant had a practically constant load of 90 amperes.

I should like to point out how important it is for effective governors to be used on the engine. I have known a case where the governors failed on a large proportion of the load being thrown off, the pressure rose from 500 to 1,200 volts, and a great deal of damage was done. Reliability, good running, and a minimum cost in repairs and attendance are always required in a mine, but extreme economy in steam consumption is not often attempted.

The steam pressures available are seldom more than 100 lbs. per square inch at the older collieries, and there is often a remarkable disregard for the fact that every ton of coal burnt, costs quite a large percentage of its actual selling value in labour, boiler repairs, and depreciation.

In spite of the above facts, in many cases a

remarkably low cost per unit generated is frequently obtained when there is a steady load extending over long hours. Capital costs, and consequently interest and depreciation, are kept down to a minimum. Attendance costs very little; for instance, an engine giving a steady output of perhaps 100 kilowatts for twelve hours a day, may be looked after by the fan engineman.

In some of the more modern plants the output is quite large, and high pressure steam and condensing are available. Gas engines supplied by coke oven gas will probably be very largely used in the near future, the reliability and economy of the modern gas engine placing it quite in the front rank among prime movers.

Cables and Distribution.—Owing to the fact that comparatively large powers are required at a considerable distance from the source of supply, and that in fiery mines a pressure of more than 500 volts is not available, the conductors have to be of ample section, and, in many cases, in order to avoid an excessive drop of pressure, the density does not exceed 300 to 400 amperes per square inch.

In the shaft it is necessary to support the weight of the cables, and this is usually done by fixing them in a tight fitting casing, or by cramping them between stout wooden cleats which are securely fastened to the walls of the shaft. Armoured cables are generally preferred for shaft work, the armouring helping to support the weight of the cable, and taking the stress off the insulation and the conductors.

In the mine the cables have to be carried in various ways, according to circumstances, but the most usual method is to hang them by means of cleats or leather thongs from the timbering. Armoured cables hung in this manner are remarkably free from serious injury, but where there is a danger of damage owing to trains running away on the inclines, or to falls of roof, they have either to be buried in the floor or specially protected.

The shaft cables are generally brought to a distributing point at the pit bottom, from which the cables to the various districts radiate. It is the best practice to build this distributing room of brick entirely fireproof, switchboards, or pillars similar to those used for tramway work, being arranged so that the cables can be conveniently coupled up. Where possible the engine planes, where trains are continually passing, should be avoided, the cables being carried along the travelling roads that are used by the men. Branches are made in suitable jointing boxes or in brickwork distributing rooms, similar in a smaller scale to that at the pit bottom. For coal cutters and portable motors, such as dip pumps, the cables are brought to a fixed switch box, and flexible cables carried on to the motors. The efficient earthing of all armouring and of the cases of switches and motors is an extremely important matter, and I am glad to say that this is required by the Home Office to be efficiently maintained. In my own practice I always employ separate cramps and conductors to make efficient contact between the outer coverings where junction boxes are fitted.

STATISTICAL ABSTRACT FOR THE UNITED KINGDOM.

The Statistical Abstract for the United Kingdom, just published (Cd. 2622), gives in succinct and authoritative form much of the data necessary to obtain a trustworthy view of the condition of the United Kingdom. The abstract opens with figures as to Imperial revenue and expenditure which show the enormous growth of the national charges in recent years. The period covered is for the years ended March 31, 1890-1, to the same date of 1904-5. In 1890-1 the receipts into the Exchequer amounted to £89,489,112, in 1904-5 they had risen to £143,370,404, an increase of £53,881,292. The revenue from Customs rose from £19,480,000 to £35,730,000; from Excise from £24,788,000 to £30,750,000; from Property and Income Tax from £13,250,000 to £31,250,000; from Post Office from £9,880,000 to £16,100,000. On the other hand, the cost of the army increased from £17,550,023 to £29,163,838; of the navy from £14,125,358 to £36,830,000; of the Civil List and civil administration from £17,637,557 to £28,843,630; of payments to local taxation accounts from nothing to £1,156,867; of elementary education from £5,293,703 to £14,235,728. Coming to particulars of Customs receipts, coal and sugar gave nothing until 1901-2; in 1904-5 coal yielded £2,052,774 and sugar £6,106,387. The yield from the tobacco duty increased as between 1890-1 and 1904-5 from £9,533,888 to £13,184,767, and from tea from £3,412,258 to £8,271,866; but the yield from wine and foreign and colonial spirits was less. So with the beer and spirit duties, both were less in 1904-5 than in the preceding year, but considerably larger than in 1890-1.

A very suggestive part of the abstract is that which gives the gross amount of income in classes brought under the review of the Inland Revenue Department for the purposes of the income tax. Taking the period as from 1891-2 to 1903-4, it will be found that the assessment of lands has fallen from £57,391,840 to £52,493,253. The fall in England has been from

£41,129,907 to £36,922,938, in Scotland from £6,318,581 to £5,852,773, in Ireland from £9,943,358 to £9,717,542, the fall in Ireland being much less relatively than in England and Scotland. On the other hand, "Houses, &c." have risen from £143,146,177 to £197,963,235, the increase in England being from £125,945,646 to £174,652,912, in Scotland from 13,425,504 to £18,556,183, and in Ireland from £3,775,027 to £4,754,140. The profits of businesses, &c., have increased in England from £229,173,045 to £317,126,464, in Scotland from £25,993,341 to £39,854,143, and in Ireland from £8,752,706 to £10,425,196. Noteworthy items are the increases in the salaries of Government, corporation, and public company officials in England. In 1891-2 salaries of Government officials in England amounted to only £16,060,000; in 1903-4 they had risen to £21,303,534. The increase in Scotland was from £291,475 to £300,870 only; whilst in Ireland there was an actual decrease, the amount paid in 1891-2 being £1,043,404, and in 1903-4 £1,025,910 only. The increase in the salaries of corporation and public company officials has been very heavy in all three countries; in England from £27,171,032 to £54,484,514, in Scotland from £3,459,230 to £6,397,133, in Ireland from £1,423,808 to £2,567,278.

It is the same with local taxation. In 1888-9 the outstanding loans of local authorities amounted to £195,442,397, in 1902-3 they had increased to £370,607,493. The expenditure in relief to the poor had increased from £8,366,477 to £13,609,570, school boards expenditure from £5,339,324 to £13,488,433; town and municipal authorities for police, sanitary, and other public works from £29,002,514 to £79,995,031; Rural District Councils spending £603,724 in 1888-9, against £1,799,632 in 1903-4. And so under every other head. The total expenditure of local authorities which in 1888-9 was £54,076,760 had increased in 1903-4 to £128,968,743.

Turning to the value of total imports from, and of total exports to the principal foreign countries and British possessions, it will be found that our trade with Russia shows considerable and fairly steady expansion. In 1890 our total imports from Russia amounted to £23,750,868, in 1904 they had increased to £31,402,838; in the same years the exports were £8,846,054 and £15,285,157 respectively, so that in the fourteen years the imports had increased by about 40 per cent., and the exports had nearly doubled. In the same period our imports from Denmark more than doubled from £7,753,389 to £16,101,808, exports increasing from £2,928,006 to £4,031,248; our imports from Holland increased from £25,900,924 to £34,689,639, but our exports fell from £16,445,992 to £12,909,663. Our imports from France increased from £44,828,148 to £51,107,046, but exports decreased from £24,710,803 to £21,702,405. With Germany, there was improvement in both directions. Imports increased from £26,073,331 to £33,944,322, and exports from £30,516,281 to £36,427,850. Imports from the United States showed great expansion, from £97,283,349 to £116,025,357, but exports fell from £46,340,012 to £39,272,433. Turning to the Colonies, our trade with Canada shows considerable expansion. In 1890, the imports amounted to £12,020,162; in 1904, they had increased to £22,621,164; whilst the exports to Canada rose from £7,809,809 to £12,248,342. The imports from Australia increased from £20,992,185 to £23,568,918; but the exports fell from £21,750,705 to £19,841,230. Imports from New Zealand increased from £8,347,430 to £12,741,510, and exports from £3,705,428 to £6,897,420. British India shows less rapid, but not inconsiderable expansion. In 1890, the imports were £32,668,797; in 1904 they had increased to £36,472,636; the exports for the respective years being £35,230,114 and £41,544,494. Taking the total of British possessions, the imports increased from £96,161,214 to £120,018,406; and the exports from £94,522,469 to £120,783,496; whilst the imports from foreign countries increased from £324,530,783 to £431,020,222, and the exports from £233,729,649 to £250,231,825. The advance in the value of the total imports and exports of merchandise at the ports of Liverpool and London has been very close. In 1890, for Liverpool, the figures were £226,218,508; and in 1904, £262,463,869. For London, in the earlier year, £233,528,425, and in 1904, £269,471,757.

Turning to population, that of Scotland exceeded that of Ireland for the first time in 1901, when it was 4,483,880, as against 4,445,630, and in 1905 the change to the disadvantage of Ireland had increased, the population of Scotland having risen to 4,676,603, and that of Ireland fallen to 4,388,107. The following figures, showing the shifting of population in the three kingdoms in the last half century are noteworthy:—

	England and Wales.	Scotland.	Ireland.
1851	17,927,609	2,888,742	6,552,385
1905	34,152,977	4,676,603	4,388,107

The rate per 1,000 of the population married in England and Wales in 1890 was 30·2, in 1904, 28·0; in Scotland, in the same years, the fall was from 30·4 to 28·6, but in Ireland there was increase from 22·3 to 23·6, which still leaves Ireland much below the rest of the kingdom. The death-rate in England and Wales, taking the same year, fell from 19·5 to 16·3, and in Scotland from 19·7 to 16·8, but in Ireland it was practically stationary, 18·2, as against 18·1. Marriages in England and Wales show a trifling decrease from 15·5 to 15·3, in Scotland a trifling increase from 13·7 to 13·9, and in Ireland a more substantial rise, from 8·9 to 10·4. The number of male criminal offenders committed for trial in England increased from 10·075 in 1890 to 11·147 in 1904, and in Scotland, from 1,909 to 2,353, but in Ireland they fell from 1,728 to 1,566. The number of paupers in receipt of relief, taking one day in the winter, in England and Wales in 1891 was 774,905, and in

1905, 914,743; in Scotland the increase was from 93,289 to 110,436, but in Ireland there was a decrease from 106,710 to 102,401. Ireland continues to furnish the greatest number of emigrants in proportion to her population. Of the number of English, Scotch, and Irish passengers that left the United Kingdom for countries out of Europe in 1904, 175,733 were English, 37,445 Scotch, and 58,257 Irish. The corresponding figures for 1890 were 139,679 English, 20,653 Scotch, and 57,484 Irish, so that with a population nearly half-a-million smaller in 1904 than in 1890 the Irish emigration was larger. The larger number of the emigrants go to the United States. Taking last year, 146,445 went to the United States, 5,486 to other foreign countries, 69,681 to British North America, 13,910 to Australia and New Zealand, 26,818 to British South Africa, and 9,095 to other British colonies and possessions.

CAPE EDUCATION: ITS DIFFICULTIES AND DEVELOPMENT.*

In 1652, under the leadership of Van Riebeek, a permanent settlement was made at the Cape of a number of servants of the Dutch East India Company, most of them soldiers and sailors, and many not of Dutch origin. Severe restrictions, imposed in the interests of the company, hampered the energy of these settlers, even sea-fishing being restrained, and the colonists being compelled to follow a pastoral and agricultural life. The Huguenot exiles in 1688, few in numbers, but numerous in proportion to the whole population, by intermarriage with the original settlers, affected strongly the subsequent character of the race, and the forcible suppression of their own language led to the modification of the adopted one into the interesting form now surviving in "the Taal."

In the absorbing cares of a new settlement, little attention was paid to education, and the office of schoolmaster was for many years combined with that of "Ziekenrooster," or sick visitor; later, with that of "precentor" to a country church. The disturbed state of Europe at the close of the eighteenth and the beginning of the nineteenth century affected the Cape, leading to its passing finally under English rule in 1806. The arrival of the British settlers in 1820 introduced a new element into the population of the Eastern Province, giving it a distinctive character to-day. Although a few schoolmasters were imported from Scotland in 1822, and the South African College founded in 1829, there was no organised scheme of education until the introduction in 1839 of the "Herschel System," based upon certain recommendations of Herschel, the astronomer, who resided at the Cape from 1834 to 1838. A Superintendent-General was appointed, Mr. Rose-Innes, who acted as inspector of all schools for twenty years. Certain "Established" schools, entirely supported by Government, provided instruction to the burgher children in English. Other schools receiving subsidy only were called "aided" schools. The great difficulty continued to be the provision of education for a thin population scattered over an enormous pastoral area. The itinerant schoolmaster was chiefly employed, teaching a few months here and a few months there, imparting in that brief period all the instruction many children ever had. The pastoral habit and the isolation of the farmhouses tended to develop that character of independence so marked in the farming community to-day. For the problem of providing education for the rural population various solutions have been offered by Education Commissions and experts from time to time, but the question is still a most serious one. The progress of education during Mr. Rose-Innes's term of office was quiet and steady, the most remarkable development taking place towards the close of that period in the appointment of a Board of Seven Examiners, the nucleus of the present University of the Cape of Good Hope. Certificates were to be granted of a standard corresponding to that of a degree in arts in Universities in the United Kingdom.

When Dr. Dale assumed office, in 1859, the "Herschel System" had practically served its purpose, and an Education Commission, appointed in the early sixties, led to the Education Act of 1865, the basis of the system in operation to-day. A local guarantee was first necessary, and the Government subsidy was to be on the principle of pound for pound for schools for the children of such parents as could afford to pay half the cost. Other schools of a lower class were designed for the poorer Europeans and the aborigines. A Board of Guarantors, appointed every three years, was responsible to the Government for the proper conduct of each school, but the weakness of the whole system lay in the want of provision for continuity and permanent buildings. The highest tribute to Dr. Dale's administration lies in his success in enlisting in the management of the schools the co-operation of so many of the best representative men in the colony. In the larger centres the system worked satisfactorily, but in small villages and country districts the life of the school was often precarious. In 1872 the appointment of two deputy-inspectors relieved the Superintendent-General of that part of his duty. In the following year came the establishment of the University, superseding the old Board of Examiners. It was to be an Examining University, like the London University, granting degrees in arts, law, &c., and certificates in land surveying. Grants were to be issued to certain institutions preparing for these higher examinations, but, unfortunately, still on the pound for pound basis.

In elementary education the lack of teachers

* Paper read by the Rev. W. E. C. Clarke, M.A., before Section L of the meeting of the British Association at Cape Town.

continued to be the great obstacle. The establishment of a Normal Institution in 1840 had produced nothing, and the attempts at developing a pupil-teacher system had also failed to remedy the defect. In 1879, the Dutch Reformed Church established a Normal College, which, under Mr. Whitton, has rendered great services in the last twenty-five years. Denominational effort had also contributed its share to the development of education, the Diocesan College at Rondebosch being the most distinguished of such institutions; but many others, although entirely unaided by Government, doing excellent work, and holding their own in competition with the more fortunate Public Schools.

Another Education Commission, in 1879, advised the division of the functions of the Superintendent-General between two officials, an increased number of inspectors, the removal of language restrictions in the medium of instruction, and the substitution of corporate bodies with rating powers for boards of guarantors. Parliament gave effect to some of these recommendations, but the guarantee system was left unchanged.

An Inspector-General of Schools, Mr. Ross, appointed in 1882, published a report of remarkable importance, pointing out especially the unique character of the Education Department as an autocracy in the midst of responsible government, and indicating the question of rural education as the chief difficulty, and the training of teachers as the most urgent want. He advised the employment of itinerant teachers for remote districts; but the longer experience of Dr. Dale led him to describe this suggestion as impracticable, as such a "vagabond" life had failed to attract competent men. He preferred the subsidising of private farm schools, with even five children enrolled. Other criticism at this time called from him a defence of the guarantee system, as providing a check on extravagance and securing the aid of those chiefly interested in the success of the schools.

Another Education Commission in 1891, besides suggestions affecting the agricultural population, technical education, and the question of school boards, made the following pronouncement on the language question:—"The choice of the linguistic medium and the decision as to whether it should be double or single seems to be a matter fairly within the parents' sphere, and neither the Education Department nor any School Board should be empowered to make either Dutch or English the sole medium of instruction in any school." Parliament had already, in 1882, removed all language restrictions.

The fact that the Superintendent-General has been an autocrat has had this advantage, that each occupant has, during a long term of office, been enabled to develop a consistent policy. The personality of the present Superintendent-General, who took office in 1892, has impressed itself strongly on Cape Education. The thorough organisation of elementary education, the development of an extensive pupil-teacher system, and the training of teachers have achieved great results. The latest Blue-book shows 2,700 schools in operation, 1,400 of these being for European children, with an enrolment of over 60,000; there are 28 inspectors, besides a number of departmental instructors in special subjects. Notwithstanding the large increase in the number of schools, the percentage of certificated teachers in those for Europeans is 71, the proportion being lowered by the lowest class of schools.

This satisfactory result has been achieved partly by the development of training-schools and other means of instruction for pupil-teachers, and also by an extensive system of Vacation Courses of Lectures by experts for the improvement of teachers in schools.

The development of boys' and girls' handiwork has been a marked feature of the new *régime*, and an annual exhibition of work and departmental examinations in this, as well as in science and other subjects, have proved a great stimulus. But as regards such tests and incentives, local examinations instituted by the University have for years provided a field for competition among all schools, and have been so sought after to assume, in the opinion of some, an undue degree of importance.

Cape education has all along developed very much on its own lines, and it has been the merit of the administration throughout to move forward less by radical changes than by adaptation of existing methods and machinery. This is evidenced in the remarkable increase in good school buildings, a result gained in spite of the want of continuity in the school committees, and without sacrificing the pound for pound principle. The Building Loan Scheme is probably Dr. Muir's most successful achievement. From the outset secondary work was combined with primary in the better schools, but during the last few years between thirty and forty High Schools have been established, with a special curriculum arranged for them, leading up to the matriculation certificate of the University. The new Education Act, while retaining committees for individual schools, will provide School Boards for municipalities and large areas, with rating powers and with control over the committees in their area. One-third of each Board is nominated by Government.

A few institutions preparing for the University certificates and degrees were subsidised under the Higher Education Act of 1874, but as the number of students increased, the idea arose of uniting the work of these separate colleges into a Teaching University. While vested interests and keenness of rivalry have hitherto prevented such unification, the development of these separate colleges has proceeded rapidly, and it seems likely that the Teaching University of the future will consist of certain constituent colleges. That these shall not be too many, and that their relation to the University shall be a satisfactory one, are the difficulties involved in this question. The Rhodes Scholarships, while benefiting the indi-

vidual holders, will also further Higher Education if made post-graduation scholarships; in the original scheme they might have tended to do actual injury to Higher Education in the colony.

A School of Mines was instituted at the South African College in 1896, and the students now complete their course at the Johannesburg Technical Institute.

While the progress of education has thus proceeded satisfactorily along various lines, it cannot be said that the position of the teacher has improved in a corresponding degree. It is true that the increased influence of the body of teachers is the most remarkable fact in modern education, and the Union of Cape Teachers in the South African Teachers' Conference, with its branches all over the country, has enabled them to speak with a strong voice on important questions, and to combine for purposes of mutual defence; but it is matter for regret that so great a proportion of time and interest has been devoted in their meetings to questions of salary, pension allowances, and other factors making for the comfort of their position. It should not be necessary for teachers to have to assert their rights and to impress their claims on the rest of the community. The new Education Act arranges for greater security of tenure and for improvement of salaries, but satisfactory provision has yet to be made for pension on retirement. "The teacher should be removed beyond fear of want and anxiety about financial concerns. The community is not in a healthy condition in which education is not held in honour."

FUR AND SKIN DRESSING IN AUSTRALIA.*

Although considerable quantities of opossum, wallaby, and other marsupial skins, together with a fair proportion of bird-skins and various kinds of fur, are annually exported from the Commonwealth, nearly the whole of which is sent out in an undressed condition, instead of being put up in a finished state and consequent securing increased employment and remuneration for those engaged in the industry. At present there are only a dozen skin-dressing establishments in Australia, yet the value of the undressed skins exported during 1904 was £186,759. This does not include skins obtained from outside the Commonwealth, nor those of sheep, rabbits, or hares; although the two latter are capable of being utilised for numerous industrial purposes. Neither is leather made from kangaroo skins included. The whole of the skins and furs dressed in the Australian States is intended for the local markets, the demand being greatest during the winter season. To make a good-sized rug, from four to five dozen opossum skins are required, the most expensive being the black furs from Tasmania. There are several kinds of opossum in Australia, the most numerous being the common opossum, which is covered with a fine long fur, of a woolly texture, and of an ash-grey colour. It is generally tracked and shot on clear moonlight nights, when its form can be detected lying on the branches of the trees frequented by it. The mountain opossum is of a larger size and its skin is consequently more valuable. It is found mostly on the great tablelands and on the confines of the snow country in which the waters of the Murray take their rise. Here the trappers arrive in winter-time and build rough huts, in which they remain for several weeks, issuing each morning in search of the tracks or clawmarks made by the animals in the soft bark when ascending the gum-trees. When these are found logs are placed in a sloping position against the trees, and soon the animals learn to run up these on their way to the upper branches, where they are easily trapped. Winter is the best time for hunting fur-covered animals, the fur then being thickest and most soft and glossy. The skins of the kaola, or native bear, a harmless animal about two feet in length, the flying squirrel, the wallaby, or brush kangaroo, and various kinds of kangaroo are obtained in immense numbers every season. Yet the animals are still abundant in the unsettled and sparsely inhabited districts; and in many places "kangaroo drives" are periodically organised for the purpose of keeping down the numbers of the strange-looking marsupial, which otherwise would leave little herbage to be cropped by the sheep and cattle in the vicinity. Platypus skins are rapidly becoming scarce, and in Victoria the platypus is protected by law all the year round. The skin resembles that of the otter, and is sometimes known in the trade variously as silver or golden otter. It is a fur very popular for ladies' winter wear. and when the coarser outer hair becomes shabby it is plucked away, revealing beneath a dark second coat of beautiful lustrous fur resembling the finest sealskin. The platypus lives and breeds in a burrow, the opening of which is in the river bank below the water. The water gradually rises until the terminus is above the water level. The burrow is thus rarely found, and the popular plan is to shoot the platypus, when, as is its custom, it is quietly floating down with the current in the twilight, or during the day when the stream is in flood and the water discoloured. The demand for hare and rabbit skins, in good condition, is practically unlimited, the fur being used in the manufacture of the felt hats now generally worn. The kangaroo skin is valued both as a fur and for the production of leather; the fur, which is soft and silky, is of a reddish colour. Although dressed furs to the value of £6,462 were imported during 1904, fur-dressing in the Commonwealth, as before mentioned, remains practically an undeveloped industry, so far as export purposes are concerned, the exports during the same year not exceeding a value of £220, yet in Victoria and Tasmania large numbers of beautiful rugs are annually made for the local markets, where they find an immediate and remunerative sale. The skins of the native cat, the

* Communicated by Mr. John Plummer, of Sydney, New South Wales.

native tiger, the bandicoot, and other small native animals, are also much used for the production of small rugs and mats.

LABOUR-SAVING MACHINERY IN CHINA.

The conservatism of the Chinese with respect to the introduction of labour-saving machinery in China is proverbial, and the chief reason given is that the introduction of such machinery would be harmful in a country where there are millions of people who will starve if there is the least disturbance of the demand for their labour. To argue that there will soon be a readjustment of things in case such machines are introduced, and that the people ultimately would be greatly benefited, is met with the reply that millions would starve while the readjustment was coming. The United States Consul at Hangchau states that while there is a great deal of truth in this argument, the Japanese would seem to be solving the problem for China by the introduction of machines which save some labour, though not enough to suddenly deprive any considerable number of people of work. One example of this is to be seen in a foot-power cotton gin, which is now quite common in some parts of the country, where the people manufacture their own cotton goods and handle their own cotton crop generally. The old method of ginning by hand is infinitely tedious. One of these foot-power gins will enable a workman to turn out about one hundred pounds a day. The machines are roughly constructed and very cheap. They will enable their owners to accomplish far more than they could without them, and at the same time will cause no disturbance. They represent a step in the direction of better things in China's cotton world, but the step is not a very long one. A similar condition is to be found in silk reeling. The Japanese have designed a silk reeling-machine constructed of wood, with a few glass eyelets and metal fittings, which they regard as a considerable improvement over the old Chinese machines similarly constructed. An expert on the Japanese machine can reel more, and better silk, in a given time than an expert can on a Chinese machine. At present, however, the Chinese seem disposed to cling to their old machines, and the mass of work done outside of the steam filatures, is done on the old-fashioned Chinese machine. The Japanese have control of the markets in the Hangchau district of China, and over most of the Chinese Empire, for many things of apparently small moment, and certainly of small cost. This is true of cheap classes of cotton goods, toilet articles, light hardware, and small goods generally. The Consul-General adds:—"It looks very much as though the Japanese were watching the markets of China very closely, not only that they may supply these cheap machines for saving some labour at the present time, but that they may thereby pave the way for greater improvements and more radical changes which the Japanese themselves will make, and, incidentally, which will be able to advance their own commercial interests. It may be relied upon that each successive stage in the changing commercial and industrial conditions of China is carefully noted and acted upon by them. At the preesent time the Japanese seem to be the only people who are giving to Chinese markets that close attention which the control of them necessarily entails."

INTERNATIONAL FIRE CONGRESS AT MILAN.

The Italian Technical Fire Brigades Federation has made arrangements to hold in Milan, in May, 1906, a congress with brigade competitions, for the prevention and extinction of fires, under the auspices of the civic authorities of Milan, and of the committee of the international exhibition to be held there next year. The congress, according to the United States Consul at Milan, is to last seven days. The mornings will be given up to work, and discussions, and the afternoons to receptions, visits to the city, excursions, &c. The Milan firemen will give exhibitions during the afternoons, and there are to be reviews of the brigades. The following are eligible to take part in the congress:—Officers of any public fire brigade in Europe or America, commanding officers of private fire brigades for the extinction of fires, and directors of companies, and those of fire insurance societies, together with all persons interested in the development of defences against fires, such as managers of public and private institutions, owners of houses and factories, or any other persons equally interested or involved. The competition will be open to all fire brigades — municipal, volunteer, or private. All foreign members who are not official delegates of governments or corporations, and who are not members of the central committee or of some of the local foreign sub-committees, must subscribe the sum of eight shillings towards the expenses of the congress. In addition to medals, diplomas, and special works of art offered by the committee as prizes in the various competitions of the congress, money prizes will be offered for rewards in the tests between foreign brigades. Everyone taking part in the congress will be presented with a decorated souvenir. All competing members will be provided with military lodgings free, if they are applied for in advance, though this is not extended to visiting officers. Horses will also be stabled free, and provision will be made for storing apparatus and material. Italian is to be the official language of the congress, but papers may be read in English if a translation is filed with the executive committee two months before the opening of the congress. Ten minutes will be allowed to each speaker. Entrance registration closes March 1, 1906, and entries for technical communications and conferences will close on February 1.

HOME INDUSTRIES.

Hops and Hop Picking.—The annual exodus of the very poor from London to the hop-fields began last week. On Tuesday, August 22, the first of a series of heavy-laden trains left London Bridge carrying "hoppers" to the Weald of Kent. It has been estimated that for the hop picking alone over a quarter of a million "strangers" come into the different hop-picking districts to do it. "There are thousands, and tens of thousands of the poorer population," said a witness before the Royal Commission in 1891, "who get a month's outing from the dark courts and alleys of London, and get fresh air, healthy exercise, and profitable employment, and one of their chief pleasures is a month among the hops, with the prospect of returning to town richer, not only in pocket but in health." Years ago serious abuses were associated with these gatherings of the "residuum" in country districts. But of late there has been great improvement in the housing and supervision of these people. They are for the most part lodged in well-built and well-ventilated "huts," and given separate rooms. These rooms have a fireplace, and are well whitewashed before the pickers arrive. They have a good supply of clean water, and there are inspectors to see that food is pure and good. Services are provided for them on Sundays, and in many of the villages coffee-stalls are organised by ladies of the village to provide coffee and soup at cheap rates. On the whole, and speaking generally, there has been marked improvement in the arrangements for the treatment of the hop-pickers.

The Acreage in Hops, and Price.—The area covered by hop cultivation in the United Kingdom was never very large. No hops are, or have been, grown in Wales, Scotland, or Ireland. The cultivation is confined to England, and mainly to the four counties of Kent, Sussex, Herefordshire, and Worcestershire. The largest acreage ever planted was in 1878, when it was 71,000 acres. Then it went down gradually to rise again in 1885 to the same acreage. Since then the acreage has fluctuated, but the tendency has been downwards. In 1894 it was 59,535 acres, in 1900 it had fallen to 51,308, and last year it was only 47,799. The price of hops fluctuates widely, but if an average of years is taken, the fall is not very marked. Thus the price in 1885, when the acreage was at its maximum, was £4 8s. per cwt., next year it fell to £2 18s. 6d., in 1889 it was £4 11s. 6d. In 1882, one of the worst crop years on record, the quotation rose to £21 2s., and in 1888 touched bottom at £2 17s. 7d. Of the 282,330 cwts. of English hops produced last year 216,807 were grown in Kent, Sussex coming next with 27,726 acres, and Hereford third with 14,101.

The Cost of Cultivating Hops.—There is plenty of suitable land available for hop cultivation, but its risks are too great to attract. Moreover, the demand for hops does not increase in anything like proportion to the growth of population. The cost of cultivation is very heavy. The following are items given by one of the best known of Kent growers, Mr. James Selmes. Taking one acre, as representative of the ordinary area of a hop plantation, ploughing costs £1; harrowing 5s.; setting out of plants 12s.; planting 30s.; hop sets (that is, the cuttings put in to raise the plants from) £5 8s.; manure £2 10s.; another species of manure is generally used, namely, rape cake, £3; the chopping of the hops round the hills 6s.; the stakes put up 12s.; tying 1s.; the stroking out of the furrows to let off the water 5s.; the rent and rates, including the extraordinary tithe redeemed £2; the extraordinary tithe 4s.; and then, before you can start your acre of hops, you must supply the poles for the hops to grow upon for the next year, which will come to £27 an acre. That makes £44 13s. This expenditure only carries as far as the first year's planting. As regards the second year, the items mount up to £40 5s., of which labour—that is to say, horse labour and manual labour—comes to something like £17.

The Profits of Hop Growing.—Roughly speaking, the hop grower has to find £40 per acre for an average crop. His profit is derived from whatever he may get per acre over and above £40. How greatly it varies is shown by the figures given above. Hop growing can only be made to pay by striking an average of years, and nearly all experience goes to show that it is in the short cropping years that the losses of other years are very often made up. For instance, take the high cost of picking alone. On very small acreage it has sometimes come to as much as £400 on a large crop, whereas upon a smaller crop of from 5 cwt. to 7 cwt. an acre instead of 18 cwt. it would be reduced by half. You cannot lay down any rule that because a crop is a small one therefore it shall be a good or bad one, or because it is a large one therefore it shall be a good or bad one. Quality, which is dependent upon the atmosphere, and price, to some extent affected by imports, are the determining factors, due regard, of course, being had to demand. And no crop is more dependent upon the weather than hops, perhaps none as much. A crop that has been all its grower could wish up to within a fortnight of maturity may be irretrievably injured by a few days of bad weather just prior to picking. In 1885, 71,327 acres produced only 509,170 cwt., in 1899 51,843 acres produced 661,373 cwt. The yield in the one year was 7·14 cwt. per acre, in the other 12·76.

Hop Cultivation and Labour.—What the shrinkage of the average under hop cultivation means to labour will be understood from a few comparative figures. There is no branch of agriculture that employs so much labour as the hop cultivation, nor half, nor even a fourth. Its abandonment would be a very serious thing to the agricultural interests of the

counties in which hops are grown, more especially Kent. The cost of growing an acre of wheat is about £4 for labour and £4 for manure. If you take 4½ qrs.—3½ is the average—at 32s., the gross value would be £7 4s. Putting the straw at £2, would give the total receipts £9 4s. Put at its highest—and it would be very high—the cost of labour for the acre of wheat would not exceed £4 per acre; the labour on an acre of hops sometimes come to £20 per acre. Labour and manure for the acre of wheat would, at the highest, come to £8, for the acre of hops £26. A hundred acres less hop cultivation in a village means from £1,700 to £2,000 less for labour. For every three acres grubbed a man must be discharged. Three acres under hop cultivation would furnish a labouring man with the means of keeping his family. It would require 50 or 60 acres of pasture to do the same thing, and not very much less of ordinary arable cultivation.

The Imports of Hops.—Whilst the home acreage under hops has diminished, the imports of hops have decreased if those of 1904 are excepted. In 1884 the imports amounted to 256,777 cwts., in 1894 to 189,155 cwts., in 1900 to 198,494 cwts., and in 1903 they had fallen to 113,998 cwts. In 1904 they ran up to 313,607 cwts., but taking the twenty years, and allowing for wide fluctuations, imports dwindled notwithstanding the decrease in the home production consequent upon decreased cultivation. The explanation is to be found in shrinking demand. The very high price of hops in 1882—£21 per cwt.—led brewers to turn their attention more closely to the cost of production. They found it possible by the use of ice to brew all through the hot weather; the consumption of beer became more rapid, it was no longer necessary to keep large stocks for many months, the public taste altered, and brighter quality of beer, less heavily hopped, came to be preferred. The result was that the proportion of hops used to a quarter of malt was reduced to an amount estimated at 1½ lb. per quarter of malt, or 15 per cent. Add a reduction due to a reduced consumption of malt estimated at 12 per cent., and the two together account for largely reduced demand and consequent fall in price.

Substitutes for Hops.—The popular idea that many substitutes are used to perform the work of hops in the manufacture, flavour, and keeping of beer does not seem to be well founded, at any rate, in the case of the leading breweries. Lord Burton has stated categorically, "We have no hop substitute in any shape or form," and he went on to say that "Practically no one here (in Burton) uses hop substitutes. Owing to the trade having become so much more a 'running' one (running beers intead of stock beers), and the increased demands for light beers, the consumption of hops per quarter has decreased." Many breweries, since 1882, are said to have made a reduction of quite 20 per cent., on account of the light beers, in the use of hops. It is not, of course, intended to convey that substitutes, such as Colombo root, camomile, quassia, cheretta, are not used in some breweries. There are firms who advertise these substitutes, and there is great difficulty in detecting the use of substitutes, but their use is comparatively small, and confined to second-rate breweries. For none of the substitutes equal the hop for the purposes for which the hop is used, which are—(1) to precipitate or render insoluble, certain nitrogenous ingredients of the wort; (2) to preserve the beer by preventing a renewal of fermentation during the time before it is fit for consumption; (3) to give it the bitter taste to which the public have become accustomed, and (4) to give it a delicate aroma. None of the various drugs advertised as substitutes for hops perform any of these functions except the third, so that most of the drugs referred to can only be used as substitutes for a small portion of the hops which would otherwise be used. New York and Californian hops are largely used by Burton brewers.

Hop Growing in the Future.—It may be gathered from the facts given above that the acreage under hops is not likely to increase. Imports keep down the price and the price must be high to give an adequate margin for risk. The profit over a series of years is not high enough to attract the speculator, and the prudent not already associated with it shrink from embarking in an industry which involves a very heavy outlay of capital that may be lost, or much lessened, by a few days unfavourable weather. Something like £40 has to be spent upon every acre of a well cultivated hop field. Now, taking the average yield of the seventeen years, 1885-1901, it was 8·40 cwts. per acre. The yields ranged between 12·76 in 1899 and 4·81 in 1888, and in 1899 prices receded to such an extent as to leave no margin of profit to the great body of growers. To cover the cost of cultivation, and assuming an average crop of 8½ cwts., the average price obtained would have to be roughly £4 15s. per cwt. to cover charges. It may be doubted whether the average sales reach that figure. The following is from the market report of *The Times,* dated August 26th, and relating to Kent and Sussex hops. "On the market, brewers, attracted by the low prices, are showing more interest in the remaining 1904 hops. Values range from 70s. to 90s. per cwt." It would seem probable that, taking one year with another, the hop-grower does not get a substantial return upon his capital, or one anything like commensurate with the risk run.

OBITUARY.

ALFRED WATERHOUSE, R.A.—Mr. Waterhouse, the eminent architect, died on the 22nd of August, after a long illness, at his residence, Yattendon-court,

Berkshire. He was born on July 19, 1830, and educated at Grove-house School, Tottenham. He afterwards became an architectural pupil of Mr. Richard Lane, of Manchester, then travelled and studied in France and Germany, until in 1853 he began practice on his own account in Manchester. His first great work was the Manchester Assize Court, the designs for which obtained for him the commission in a hotly contested competition in 1863. The buildings from his designs in Manchester, Oxford, Cambridge, Leeds, Liverpool, and especially London, are many, and the Natural History Museum, at South Kensington, is perhaps the best known of them all. Many of his large buildings, such as courts of law, town halls, hospitals, museums, clubs, the Central Technical Institute, Prudential Assurance Offices, required special skill in the planning, and in this department Mr. Waterhouse was a recognised master. His earliest works are in the style of the Gothic revival, but later he considerably modified this, and at all times he exhibited great originality of treatment. He was elected A.R.A. in 1878 and R.A. in 1885. For a time he was treasurer of the Royal Academy. He became a member of the Society of Arts in 1901.

GENERAL NOTES.

CHEAP CLOTHING IN CHINA.—It does not cost much to clothe a Chinaman in Wuchow. Reporting on the trade of the place, Mr. Acting-Consul Williamson (No. 3449, Annual Series) says that the nankeens worn are woven from Indian yarn and are very popular amongst the poorer classes in the province, since, in spite of the large and increasing import of foreign piece goods, nine-tenths of the people are too poor to wear anything but native cloth, which, though not any cheaper than the foreign article, is far more durable and suitable for all seasons. A complete suit, consisting of coat and trousers, costs, made to order, about 3s., and worn daily will last a whole year. A couple of such suits, worn one over the other in winter, is about all the clothing the average peasant possesses. Many of them weave the cloth themselves from Indian yarn, but not to the same extent in Kuangsi as in other provinces, owing to the laziness of the natives. It is probably from this reason that at the Industrial Institute at Wuchow, the weaving of cloth has been the only industry of the many attempted which has been found to pay. It is produced at a cost of 1½d. a yard, 13 inches wide, and finds a ready sale at 1¾d. a yard. The weaving is done entirely by boys between 12 and 15 years of age.

TRADE WITH MOROCCO.—Mr. Consul Maclean's report on the trade of Dar-al-Baida, for 1904 (No. 3443, Annual Series) shows that the United Kingdom maintains her position in the markets of Morocco, Germany being third in relative importance, France coming second. Of the coast trade of the district, the United Kingdom took 47·27 per cent., France 21·06 per cent., Germany 15·66 per cent. The per centage of the total trade that fell to the United Kingdom was 47·27, against 21·06 for France, and 15·66 for Germany. The per centage was much the same throughout the consular district, which includes Rabat, Dar-al-Baida, Gaffi, and Mogador. Owing to the drought, the exports for the present year are likely to show a considerable falling off. Mr. Consul Maclean says that manufacturers of domestic sanitary appliances, and of roofings suitable to withstand the hot sun of summer and the heavy rains of winter, should direct their attention to the potentialities of the market. There is no great opening at present, but trustworthy agents should be provided with samples of strong, simple, and inexpensive goods. House and store fittings, such as locks, hinges, window frames, &c., are likely soon to be required, and there is a growing market for cheap lines of ready made clothes for men and youths, owing to Morocco Jews and Jewesses discarding their native dress in favour of European apparel.

EMIGRATION.—During the quarter ended June 30th, 134,745 emigrants left the United Kingdom for places outside Europe. Of these 81,843 were natives of the United Kingdom, of whom 51,356 were English, 13,515 Scottish, and 16,972 Irish. The proportion of emigrants accredited to the several parts of the United Kingdom per million of the respective estimated population were as follows:—England, 1,504; Scotland, 2,890; Ireland, 3,866. But whilst Ireland retains the lead as the great emigrating section of the Kingdom, proportionately the Irish emigration shows decrease. The proportion of English emigrants showed an increase of 17·1 per cent., the comparison being with the averages in the three preceding second quarters, the Scottish an increase of 31·1 per cent., and the Irish a decrease of 5·2 per cent. Turning to the statistical abstract of the United Kingdom, it will be found that up to the end of 1904, a very large proportion of the emigrants of British nationality went to the United States, and there is no reason to suppose that a large majority are not going there this year, but in 1904, no less than 69,681 out of a total of 271,435 went to British North America, and probably this year's figures will show an even larger proportion. Last year the number that went to the United States was 146,445.

MEETINGS FOR THE ENSUING WEEK.

WEDNESDAY, SEPT. 6...Institute of Sanitary Engineers, 11, Bloomsbury-square, W.C. Election Committee at 3½ p.m. Organising Committee at 5 p.m.

Journal of the Society of Arts.

No. 2,755. VOL. LIII.

FRIDAY, SEPTEMBER 8, 1905.

NOTICES.

EXAMINATIONS.

The Programme for 1906 is now ready. The price of the Programme (containing the previous year's papers and the examiners' reports on the work done) is 3d. Copies can be had at this price on application to the Secretary, Society of Arts, Adelphi, W.C.

The Examinations are now arranged under the following stages:—Stage I.—Elementary; Stage II.—Intermediate; Stage III.—Advanced.

The subjects include: — Book-keeping, Accounting and Banking, Shorthand, Type-writing, Economics, Précis-writing, Commercial Law, Commercial History and Geography, Arithmetic, Handwriting, and Modern Languages.

The Examinations will commence on Monday, April 2, 1906.

Before 1905 the Examinations were arranged in two Grades—Preliminary and General. The Preliminary (Grade I.) corresponds with the present Elementary Examination (Stage I.). The Third-class, and the lower part of the Second-class of the former Grade II. correspond with the present Intermediate, or Stage II., and the First-class, wlth the upper part of the Second-class of Grade II., correspond with the present Advanced, or Stage III.

The papers now set are of the same character as those of the previous years, which will therefore, as hitherto, form a useful guide to the nature and scope of the Examinations.

Candidates who have not previously passed in the Society's Examinations are strongly recommended to enter in the first instance for the Intermediate Stage.

The only alteration of importance in the Examinations for the present year is in Shorthand. Formerly all the different Stages of Shorthand were taken on the same evening. The different Stages will now be taken on two evenings: Advanced (First-class 150, Second-class 120 words per minute), and Elementary (50 words) on one evening; Intermediate (First class 100, Second-class 80 words per minute) on another.

The alterations originally proposed have been considerably modified in view of the opinions expressed by the various local Committees, and their executive officials, to whom they were submitted. It is hoped that the system now adopted may meet the requirements of the majority of the candidates.

Swedish has been added to the list of subjects in Stages II. and III., and the examination in Danish will in future be in Danish and Norwegian.

In the Advanced and Intermediate Stages First and Second-class Certificates will be granted in each subject.

In the Elementary Stage Certificates will be given in each of the subjects enumerated. These will be of one class only.

Certificates of proficiency will be granted in each grade to Candidates who pass in certain specified subjects during a given period.

In Rudiments of Music Higher and Elementary Certificates will be given; in Harmony Higher, Intermediate and Elementary Certificates.

A fee of 2s. 6d. will be required by the Society from each Candidate in each subject in the Advanced and Intermediate Stages, and in the Elementary Stage a fee of 2s. for one subject, and 1s. for each additional subject taken up by the same candidate. The fees for Harmony and Rudiments of Music are the same as for Stages II. and III.

Medals and Prizes are offered in each subject in Stages II. and III. Full particulars will be found in the Programme.

Examinations are also held in the Practice of Music, and Vivâ Voce Examinations in French, German, Spanish, Portuguese, and Italian. For information as to these examinations reference should be made to the Programme.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

USES OF ELECTRICITY IN MINES.

By Henry Willock Ravenshaw,
Assoc.Mem.Inst.C.E., Mem.Fed.Inst.M.E.

Lecture II.—Delivered May 22nd, 1905.

In my last lecture, I went into the question of electrical transmission of power. I will now take a few of the minor applications, some of which such as signalling, are almost of equal importance.

Electric Lighting.—The electric lighting of a colliery is generally independent of the power plant, and, as a rule, a continuous service is maintained. A pressure of 220 volts direct current is usually employed, and the shaft cables (in some cases 600 to 1,000 yards long) have to be of ample section to prevent an undue drop of pressure. As a man is required to attend to the ventilating fan engine night and day, the electric lighting dynamos are frequently so placed that he can look after them.

Owing to the large amount of dust from the surface works, and the general dampness of the atmosphere due to steam from the exhaust of the winding engines, it is very difficult to maintain a good insulation resistance on the surface. It is, therefore, excellent practice to have a separate dynamo for supplying the underground lighting. It is a curious fact that even in a damp mine it is easier to maintain a good insulation underground than on the surface. Where motors are used at a considerable distance from the pit bottom, it is very convenient to light their engine rooms and the adjacent roadways by lamps, in series, on the power mains. Electric accumulator lamps are sometimes employed, but they are not very largely used, the extra weight and first cost being against them.

For officials and inspections, small dry battery hand lamps are very convenient as an auxiliary to the ordinary safety lamp. Electricity has also been applied to the lighting of the ordinary oil safety lamps, and Messrs. Johnson, Clapham, and Morris have kindly lent me a lamp-lighter which shows the expedition with which a number of lamps can be lighted. The arrangement consists of a single cell accumulator, and each lamp has a short piece of wire close to the wick connected to studs which can make contact with the battery circuit. When the current passes through the wire it becomes incandescent, and lights the lamp. When the men are going down the pit, a very large number of lamps have to be lighted for them, and as they all have to be sealed and examined a great deal of oil is saved where an electrical arrangement can be used to light each lamp as it is issued.

Signalling.—The earliest forms of signalling were by word of mouth, and in some pits in Belgium this custom survives in the form of a short prayer for their safety, which is sung out by the banksmen when men are descending. In some parts of Durham, the banksman sings out, "throw nought down." The somewhat primitive "rapper," where a hammer is lifted by a wire, and allowed to drop on a piece of loose iron plate, is still largely used, but for long distances these have to be worked by relays of men, and the work is very arduous. Electric signalling bells have now become very popular, and in some cases as many as twenty primary cells are used on a circuit. In order to prevent danger from sparking at the contacts, the new Home Office rules limit the pressure on signalling circuits to fifteen volts in fiery mines. The bells and keys are generally fitted so as to be dust and damp tight. On roads where mechanical haulage is employed, two bare wires are stretched overhead at such a distance that they can be pinched together with the hand. These wires are connected to a bell circuit so that signals can be transmitted from any point on the roadway to the engineman. The cost of primary batteries in a large colliery is considerable, and amounts to as much as £80 a year for material alone. Telephones are largely used, but it is remarkable that until quite recently a large number of collieries were not fitted with them.

Shot Firing.—Two systems are in general use for electrically igniting the fuses, namely, the low tension and the high tension. In both cases magneto generators are generally used which are turned by hand, but, in the case of shaft sinking, shots are frequently fired from the lighting circuits. In the case of the low tension, the current heats a fine platinum wire which fires the detonating charge. A pressure of only a few volts is employed, and when several shots are to be fired the fuses are arranged in series. With this system it is possible to test for continuity of circuit, but this advantage is somewhat discounted by the fact that it is practically impossible to dis-

tinguish between a complete circuit and a short circuit. Batteries, either primary or secondary, are sometimes used for low-tension fuses. With high-tension ignition the points are a short distance apart, and they are generally coated with conducting and inflammable chemicals. A pressure only of from 30 to 150 volts is required, and it is probable that an arc is actually formed. In this system the fuses are arranged in parallel. High-tension fuses are somewhat cheaper than low tension, and appear to be the more popular with the officials who have to use them.

Alternating and Direct Currents.—Both direct and alternating currents have been largely used in mines with success, but experience points to the fact that the alternating system is the more suitable. Where large powers are required, the difficulty in breaking heavy direct currents in enclosed boxes is very great; oil switches cannot safely be employed owing to the quick break causing a heavy rise of potential in the circuit, and the same objections apply to magnetic blowouts.

With alternating currents oil switches can be safely used, and this one point alone is sufficient to give that system a great advantage. The absence of brushes and the possibility of using squirrel cage rotors is also an advantage, although the modern motor gives very little trouble at the commutator.

High pressures have no great advantages for use inbye, as the distance from the distributing centre is not, as a rule, more than two to three miles, or well within the economical limit for a pressure of 500 volts.

Precautions.—It is of absolute importance that the safety of the mine is ensured, and a very long step towards immunity from accident is to put down a first rate plant in the first place.

In a colliery where capital expenditure is of necessity kept low, there is a temptation to buy in the cheapest market. Electrical machinery, however, has been reduced in price to a remarkable extent, and there is no possible excuse for those responsible risking the lives of men in their charge by purchasing in the very lowest market. I speak strongly on this question as I have seen a great deal of dangerous rubbish in use, and I am glad to say that the report of the Home Office Committee made a very strong point of this question.

Next to a good plant, proper maintenance is of the greatest importance, the insulation of every detail being properly maintained. All plants, particularly in safety lamp mines, should be systematically and independently inspected several times a year. In safety lamp mines motors should always be placed in the intake air, and in my own practice, whenever possible, the motor rooms are used as lamp-lighting stations, so that special precautions are taken to keep them free from gas. The question of enclosed motors is an important one, and the experiments made by Mr. W. E. Garforth, and described by him in his evidence before the Home Office Committee, appears to me to cover the whole ground. The experiments are fully described, with eleven fine photographs, in the minutes of evidence taken before the committee, and the conclusions arrived at are as follows:

It is possible to run an entirely enclosed motor, the covers being machine faced and efficiently gas tight, in an explosive mixture for one hour without ignition. An unenclosed direct current motor will ignite gas. If an enclosed motor is surrounded for 14 hours by an explosive mixture the gas may diffuse into the case and cause an internal explosion. The internal explosion above-mentioned will not of necessity ignite the external mixture.

Home Office Committee and Rules.—In 1902 a committee of six members was appointed by H.M. Principal Secretary of State of the Home Department to inquire into the use of electricity in coal and metalliferous mines, and evidence was first taken on November 26th, 1902; 6,958 questions were put to the 57 witnesses who were invited to give evidence. A report was issued on January 19th, 1904, including a code of rules which it was suggested should be adopted. Special rules, which differed considerably from those originally suggested, were issued in February, 1905, by the Home Office, and these are now in force in this country.

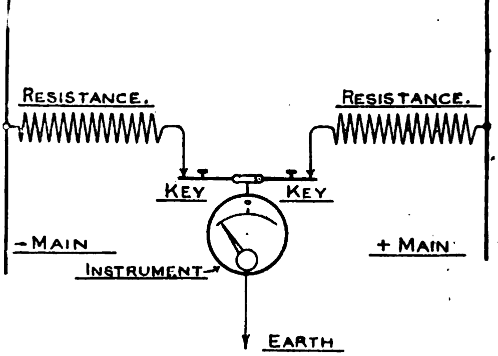
Although any new regulations are sure to cause a certain amount of hardship on those who come within their sphere, colliery owners having properly-installed plants have been put to very little expense in complying with the new rules. Rule 6, Section III., which requires that leather or other flexible material shall be used for suspending cables underground, is the only one which is likely to cause any real hardship. This rule is of somewhat "cast-iron" character, as hundreds of miles of cables are already fixed up by cleats, and in many places, especially where there is very little room, competent colliery

managers are of opinion that a flexible suspension is not suitable.

I have already pointed out the importance of the proper maintenance of insulation, and the new rules require that this point should be specially safeguarded. Rules 6 and 7, Section I., require that the leakage current shall not exceed one-thousandth of the maximum supply current, and earth detectors are required to be connected up to show immediately any defect in the insulation of the system. The readings from these instruments have to be recorded daily.

The leakage current permitted does not err on the side of stringency, as in a properly-maintained plant it should not exceed one ten-thousandth. The detector specified has presented a difficult problem to the manufacturers, but they have risen to the occasion and produced instruments which comply fairly well with the specification. None of these instruments actually comply with the letter of the rule, but they usually show when there is a serious leak, and by actuating a small switch the pole can be located and a fairly accurate measurement obtained. The simplest arrangement for direct currents is perhaps that shown in Fig. 10, where a high resistance

FIG. 10.



is connected across from positive to negative pole, and the centre connected to earth through a sensitive polarised instrument. To obtain the insulation resistance one side or the other of the resistance is disconnected, and the deflections noted. To obtain an accurate result, a calculation must be made from the two readings, or, better still, a table can be used from which the results can be read.

This system does not accurately show leakage in all cases, without a certain amount of manipulation, as for instance, where the insulation resistance of both poles, whether high or low, is equal, no deflection is shown. If properly used, however, the arrangement is a great safeguard against mishap. For three-phase circuits, Mr. Raphael proposes to make a star connection between the phases through high resistances, connecting the centre through an instrument to earth. By disconnecting the phases in rotation the earth can be located. This instrument has defects somewhat similar to that for direct currents, but they are both in advance of their predecessors. The following rules may be noted:—Where safety lamps are required, the pressure is limited to 650 volts, and under. Telephone communication has to be maintained between the surface and the distribution centre. Open motors are allowed in properly ventilated places. The pressure for signalling circuits is limited to 15 volts. (There are 56 rules divided in eleven sections.)

Costs.—The questions of capital expenditure and running cost are of the greatest importance, and it may be safely said that where proper economy has not been exercised in putting down a plant, there will be likely to be found heavy working costs and unreliable running.

For colliery work the plant must be of the highest quality but simplicity of design is of the greatest importance. Where steam engines are used an excellent electric generating plant, suitable for a works or colliery, can be put down for £22 per kilowatt output. A gas engine plant using coke or anthracite would cost £24 per kilowatt, and if coke oven gas is used £22 per kilowatt. An exhaust steam plant of the Rateau type would probably cost from £18 to £20 per kilowatt.

These figures are taken from actual practice and make no allowance for spare plant. A margin of about 20 per cent. is generally allowed for spares. Depreciation, and interest on capital expended, are items that are of the greatest importance in calculating costs, and it is an astonishing fact that until quite recently the question of depreciation has been practically ignored by many of the large electricity supply undertakings. Municipal authorities have actually borrowed money to be repaid in from 30 to 40 years to purchase machinery that has become obsolete and been sold for practically scrap price in less than a third of that time.

In commercial undertakings of high standing this question is always taken into careful consideration, and true costs cannot be obtained unless at least 5 per cent. be allowed for depreciation and 5 per cent. for interest on capital. Where there is a low power factor,

which is usually the case with a public supply, these items will be found to exceed considerably the total working costs, but, in a mine, where the first costs of a generating and distributing plant are comparatively low and a good load factor is generally maintained, interest and depreciation should not exceed 0·25 penny per unit.

With regard to coal consumption it must be remembered that although coal may be cheap, boilers cost money to put down and maintain. I have gone rather thoroughly into this question, and I find that, on an average, for every ton of coal burnt, the costs for labour, boiler repairs, depreciation and interest on capital, amount to at least 2s. 6d., consequently, even if the coal cost nothing, a ton saved per day would mean a saving of at least £40 per annum. In large collieries from 50 to 80 tons a day are burnt under the boilers, and in many cases it is practically certain that this consumption could be reduced by one half.

FIG. 11.

PEEBLES ILGNER FLYWHEEL COMPENSATOR (Bruce Peebles and Co., Ltd.).

The following consumptions if obtained all the year round are not likely to be improved on with a 200 kilowatt plant working 16 hours a day:—Steam engines, 5 lbs. per kilowatt

FIG. 12.

ELECTRIC DIP PUMP IN HEADING (3 ft. 6 in. high).

FIG. 13.

ELECTRIC LONGWALL CUTTER (J. Davis and Son, Ltd.)

gas engine with anthracite, 1·85 lbs. per kilowatt; gas engine with coke, 2·25 lbs. per kilowatt.

The costs with a good load factor should not exceed:—

Coal and boiler or producer charges	0·20d.	per unit.
Labour, stores, repairs	0·15d.	,,
Depreciation and interest	0·25d.	,,
	0·60d.	

With a plant of double the size, the costs can be reduced to 0·5d. per unit. When it is considered that with a 200 kilowatt plant working for ten hours a day, a saving of 1-10th of a penny per unit means £250 per annum, the importance of economy is evident. The fact that the cost of electrical machinery has been enormously reduced in the last ten years, is of great advantage to power users, and has given an enormous impetus to electrical transmissions. A slow speed 40-h.p. motor which used to cost £220, can now be bought for £100 or about £2 10s. per h.p., a great contrast to high-class steam engines which cost about £5 per h.p.

In putting down an electrical power plant the cost of the generating station must be considered, but it is an interesting fact that where there are a good many motors working on variable loads the demand seldom exceeds one-half of their aggregate maximum capacity. For instance, a 500 horse-power dynamo will generally be sufficient to supply current to 1,000 horse-power of motors.

I am convinced that a colliery of fair size can generate electricity for its own use at a considerably lower rate than a public supply can afford to sell it at a profit, if a proper allowance is made for depreciation in both cases.

The history of this application hardly goes back further than twenty years, and I am glad to say that practically all the pioneers are still hard at work. Mr. Frank Brain, of Trafalgar Collieries, in the Forest of Dean, is probably the earliest pioneer, as he used electric signals as far back as 1866, and an electric pump in 1882. Most of the early work from 1885 to 1891 was done in this country by Messrs. Immisch, Scott and Mountain, and Goolden and Co., and I can recall the names of Messrs. L. and C. Atkinson, Selby Bigge, S. Corlett, M. Deacon, W. C. Mountain, and Albion Snell as being prominent workers in those days.

The advantages of the use of electricity in mines is in many cases obvious, and it is certain that as new collieries are opened out, and old ones reorganised, the electric motor will be almost universally used; in fact I feel fairly safe in saying that where compressed air has to be used the air compressors of the future will be electrically driven in the mine itself. With regard to winding, a great deal has to be done in devising simple and economical electrical methods before they are generally adopted, but it is more than likely that this class of plant will be of great importance in the future. Electrical driving is being almost universally adopted all over the world, for its all-round economy and convenience, and these advantages are being rapidly appreciated among mining engineers.

ELECTRIC BAR COAL CUTTER (Mavor and Coulson).

[Figs. 11, 12, 13, and 14 illustrate various applications described in the first Lecture.]

FROM CHENGTU TO THIBET.

Last year Mr. Alexander Hosie, His Majesty's Consul-General at Chengtu, was instructed to make a journey to the eastern frontier of Thibet, and his report upon it, now published as a Parliamentary Paper (China, No. 1, 1905), is an interesting description of an unknown country. The great highway connecting Chengtu with Lhassa passes westward through various cities, and across the upper waters of the Yang-tsze to the Ning-ching mountains, which at this point form the boundary line of Thibet and China, the distance by road from Chengtu to the frontier being about 600 miles, and to Lhassa 1,500. Mr. Hosie did not attempt to go beyond the frontier. Leaving Chengtu on the morning of the 28th July, 1904, he reached the frontier on September 16, so that it took him seven weeks to do the 600 miles. "There was perfect silence," he writes, "as I went up to the boundary stone which marks the frontier of the two countries, but I could see a fixed determination on the part of the troops to resist any attempt on my part to cross into Thibet. The boundary stone which stands some 30 yards to the north-east of an obo by the road side is a well worn, four-sided pillar of sandstone, about 3 feet in height, each side measuring some 18 inches. There was no inscription on the stone, and when unthinkingly I made a movement to look for writing on the Thibetan side the Chinese officials at once stepped in front of me and barred the road to Thibet." The road travelled by Mr. Hosie is that taken by the Chinese Imperial Residents for Thibet, who occupy several months on the journey; along it devout pilgrims, eager to look upon the face of the Dalai Lama, advance, some by continuous genuflections and prostrations taking years to reach their goal; and over it dash Imperial couriers who, by travelling night and day, are able to carry messages from Lhassa to the nearest telegraph office at Ta-chien-lu, some 1,300 miles, in less than twenty days.

The journey was monotonous, and the people uninteresting. Most of the men become priests, of a sort. "In a land," writes Mr. Hosie, "where each family devotes one or two of its sons to the priesthood, female infanticide is unheard of, and woman is a very valuable asset. She milks the cattle before they are sent out to graze in the early morning, and on their return in the evening. This done, she slings the empty wooden water butt (some 2½ feet long by 18 inches or more in diameter) on her back, and runs off to the nearest stream for the day's water supply. Filling the butt by means of a birch-bark baler, she balances it on her back, the bottom resting on an adjustable pad of cloth or fibre, and the upper part kept in position by a rope of raw hide thong encircling butt and chest. This visit to the stream she repeats several times during the morning, storing the supply in a large wooden vat. She makes the butter, an important article of food in a country whose altitude defies the growth of oil plants, and where the difficulties and cost of transport are prohibitive, in the wooden churns of our forefathers without, however, that care and cleanliness which they bestowed upon it. She prepares the food, she weaves the cloth, and she attends to the many other duties of the household, besides engaging when necessary in the usual outdoor work of the farm." The Thibetan women are not attractive. They wear the Litang forelock hanging down to the tip of the nose, and their hair is done up in numerous plaits which straggle down the back, but are hidden in the case of the widow and wife by an elaborate head-dress. Butter is their hair oil. Mr. Hosie joined a family at one of their meals, and took a minor part in its preparation. Husked barley is baked for a short time in a flat cooking-pot and then ground into flour in the usual stone mill worked by hand. The barley meal—called tsamba—is collected and placed in a hide bag. A handful of brick tea is thrown into a large copper cooking-pot narrowing slightly at the neck. A little cold water is poured into the pot, and as soon as it comes to the boil more cold water is added. When this in turn boils the contents are removed by copper ladles and passed through a conical strainer into a small churn wherein some butter has been dropped, and a little salt is added. The tea and butter are churned together, and the compound ladled out and passed through a strainer into a large copper teapot, whence it is poured into the usual wooden cups. "We all sat on the floor," says Mr. Hosie, "holding the cups in our hands. Each sipped about a third of the buttered tea, and then took a handful of tsamba from the hide bag and placed it in the cup, kneading the whole into a dough with the fingers. There are no spoons, forks, or chopsticks, and pieces of the warm dough are simply carried by hand to mouth. This is the ordinary Thibetan meal, the cups being replenished at will." Occasionally beef or mutton is eaten in the early morning or the evening; it is sometimes eaten raw. So with vegetables such as turnips, they are eaten uncooked, and a favourite tit-bit is the green-husked grains of barley, which are tossed into the mouth with much dexterity.

The country between Ta-chien-lu and the Thibetan frontier is a land of mountain, forest, valley, and river, rarely falling below an altitude of 11,000 feet above the sea. Grass and certain wild flowers seem to grow at any height, but the limit of cultivation of any kind is under 13,000 feet. In valleys between 12,000 and 13,000 feet barley, wheat, and oats, as well as small round turnips, are grown, but immediately that height is exceeded grass covers the land. Even when working cultivable areas the Thibetan seems to be a poor farmer. With his team of yak, or a couple of yak harnessed to his one-handled wooden plough, he does little more than scratch the surface of the ground, and he fails to warm and sufficiently enrich his fields with his abundant stable manure. The country is far more pastoral than agricultural. Tent life, with its horse-breeding and cattle and sheep raising, is more to the taste of the people than the cultivation of

fields. Mr. Hosie says that anyone who has seen Highland cattle will, by imagining clumsy animals about double the size, have a very fair idea of what yak are. If he will further imagine that they are nearly all black, that their black horns have a simple semicircular curve, and that they have long, very bushy tails, his idea will be still nearer the mark. They are slow, plodding animals, but well fitted for work on the mountain roads. Yak milk is the milk of the country and provides butter and curds. The dzo, or Chinese pien niu, the cross between the yak and the ox, is also used as a pack animal, and is noted for its strength and endurance. It is, however, much rarer than the yak.

The religion of the people is little more than mechanical. They have their lamaseries, where, or in the street, they may engage priests to perform their religious duties—chant the sacred books, beat drums, and turn prayer cylinders or wheels. The latter are always turned from right to left, whether by hand, water, or air. They vary in size. In the house of a headman Mr. Hosie counted over twenty let upright into different walls. They were made of raw hide from 3 feet to a foot in length, and from a foot to several inches in diameter. They were filled with written or printed prayers, and the turn of a cylinder by hand is equivalent to uttering a prayer. Small cylinders for hand use are made of silver, copper, and white metal, some of them of beautiful workmanship. Mr. Hosie found it difficult to purchase specimens, the reason given being that they are supposed to be cremated with their owners. Cylinders turned by water-power are common, and they are sometimes fitted to small windmills inserted in the apertures, which do duty for chimneys on the house-tops. The draught is sufficient to turn mill and cylinder. On the road members of Mr. Hosie's escort were always muttering what he took to be prayers, and even the women carrying water were usually reciting in a low voice something only intelligible to themselves. The obo have also a religious significance. They are of two kinds. On the mountain passes they consist of mere conical heaps of stones thrown by passing travellers and decked with prayer flags on their summits. Each stone is a thank offering to the gods for safety. In the villages they were more elaborate, usually oblong, and built of stones, or alternate layers of turf and stone, some three feet or less in height, shaped like a sloping roof, with slabs of slate or marble, inscribed with whole prayers or the single letters making up the invocation, *Om mani Padmé Hum*. Rising from the centre of this heap of prayers there is usually a rude carved pole some 6 feet high, but no prayer flag, for the prayers carved in the lamaseries and sold to the people lie below. The letters, sometimes accompanied with figures of animals, fishes, snakes, and frogs, are common, and are not unfrequently painted in various colours. Burial, cremation, exposure to the birds of the air, and throwing into the river are the methods employed in disposing of the dead in different parts of the country. Education is confined to the lamaseries, and even then few of the priests can do more than read their sacred literature, and that with the greatest difficulty. Writing is an art which few have learned.

Brick tea is the great import. The total annual quantity of brick tea carried to Ta-chien-lu for consumption to the west of the city is approximately 11,377,333 lbs., of the value of 948,591 taels. The principal export from Thibet is musk. The pods, with an inch-wide fringe of skin and hair, are brought to Ta-chien-lu, where they are trimmed, cleaned, and made ready for the Chinese or foreign market. The fringe of skin and hair is removed by scissors, and, in the case of musk intended for the Japanese market, the hair round the trimmed pod is carefully singed. There are several tests for adulteration. If the smell is not satisfactory, and any doubt exists as to the genuineness of the contents, a small sharp scoop is thrust into the pod and a few grains extracted. The grains are put in a cup of water. If they remain granular the musk is genuine; if they melt it is false. Another test is to place a few grains on a live piece of charcoal. If they melt and bubble on the red surface, the musk is good; if they at once harden and become cinder, the musk is adulterated. The trimmed and clean musk pods are valued at from 15 taels to 16 taels per Chinese ounce (1⅓ oz. English), and the total amount annually cleaned at Ta-chien-lu for the Chinese and foreign market is estimated at 1,100 to 1,200 catties of the value of 300,000 taels. The banks of the Li Chu, in the Litang Plain, are very rich in gold, but the lamas of the Litang lamasery are opposed to, and prevent its exploitation. Thibet and the border lands are famed for the production of certain medicines, animal and vegetable, including the mixture of animal and vegetable, known as *Condiceps sinensis*. Raw borax comes from Thibet, and is converted into pure borax at Ta-chien-lu. Furs are represented by the fox and the lynx. The total of exports and imports are valued at only 1,722,591 taels; 669,100 taels representing the exports from Thibet to China, musk accounting for 300,000 taels, and gold dust for 192,000.

THE HIGHER EDUCATION OF WOMEN IN SOUTH AFRICA.*

Limitations of the Term.—In almost any country, and assuredly in any other land where English is the language of the State and of schools, the connotation of the term, "higher education," would be strictly limited to college and university work above the grade of matriculation. But in South Africa, a comparatively new country, the term may be allowed a somewhat broader and more general significance, so that it may be understood as including—(1) Secondary

* Paper read by Miss E. M. Clark before Section L of the British Association at Cape Town.

or high-school education; (2) normal or training-school education; (3) collegiate or university education. From the outset certain peculiarities characteristic of the country should be borne in mind: (1) the differences of standard, nationality considered, as among Colonial Dutch, Colonial English, and real Europeans; (2) the differences of standard, locally considered, as between town and country education; (3) the popularly accepted differences of standard for boys and girls.

Provision for such Education.—The number of schools having the technical right to the name "High School" is comparatively small; but all of the "A 1" public schools are doing some work of this grade, while many of them are offering instruction in all the highest standards, including matriculation. Statistics for 1904 report 2,331 pupils in High School grades, without specifying as to sex, though here it is safe to say that the girls are in the minority. . . Very different in this respect is the case with the three "European" Training Schools for pupil-teachers and others, which report a very striking majority of female students. Of these one is in the eastern division, and two are in the western. The specific object of these three institutions is that of giving instruction in the principles and methods which lie at the base of successful teaching: 284 students represent the enrolment for last year. . . In four institutions of College grade, preparing for the Cape University examinations, young women are now following the prescribed courses of study; the total registration, however, is not over fifty, and a very large proportion of these women students are in the intermediate class.

Changes in Standard.—Forty-five years ago there existed in the whole country only one large school for girls; twenty-five years ago at least six had been founded, and were in successful operation. No one of these, however, at that time was doing anything like college work, nor was matriculation then regarded as a *school* examination. Reading, writing, elementary arithmetic, with "accomplishments," had been up to that time considered all that was necessary for a girl to know for her own good, while there existed little or no conception of training or education for the sake of imparting knowledge to others. . . . The development has been slow but steady. The grade-standard has advanced, as has also the generally accepted standard of public opinion, in both city and rural communities. One very important element in this advance, so far as the education of women is concerned, has been the growing necessity for self-support, with the increasing strictness of requirement on the part of the Department of Education, a strictness which has been applied in due proportion to schools of all grades. According to the official report of the Superintendent-General for 1904, the percentage of "female teachers in the seven most important classes of schools," varies from 49·13 to 89·33, an indication of a great change during the quarter of a century in the general attitude toward the question of the right of young women to teach and to be taught.

The University System.—The University of the Cape of Good Hope is exclusively an examining body, having the right to grant academic degrees. Five teaching institutions or colleges prepare students for the examinations leading to the grades—Intermediate, B.A., and M.A. There has never been on the part of the University any discrimination of sex in the matter of eligibility to the examinations given, or the degrees conferred. In most of the Colleges co-education exists, while during the past few years several scholarships based on competitive examinations have been taken by women.

The Situation and the Outlook.—With reference to the future, even the immediate future, several important topics suggest themselves as worthy of consideration—(1) the actual supply of teachers in relationship to the demand; (2) the advantages and disadvantages of bringing in trained educators from England and elsewhere; (3) the possibilities of partial self-support for women students; (4) a study of the methods of higher education here and in other lands; (5) suggestions as to possible future developments, regard being had to the special conditions of the country. . . . These points, however, can be only named, not developed, in so brief an outline.

Causes of Small Increase.—The slow advance in the number of women students registered by the Colleges of this country is usually attributed to one of two causes: (1) lack of interest; (2) lack of means. Into the reason first named may be read the meaning—lack of desire for the advantages offered, or of appreciation of their real value; several good authorities in the educational world regard this as the fundamental reason. Others, however, are equally sure that the expense of a College course, or even the immediate necessity for bread-winning, lies at the root of the fact that now, nearly twenty years after the granting of the first Cape University degree of B.A. to a woman, there are throughout the country fewer than fifty women students preparing for the University examinations. In other lands, where the paternal governments are less fartherly than here, much more is done in the way of self-support by undergraduates of both sexes, even while pursuing their studies. Yet it must be acknowledged that the difficulties are greater here than in those countries where a student who has "worked her way" from matriculation to B.A. is not an anomaly.

The End—the Means and the Woman.—The higher education of women is a comparatively new factor in the growth of this country, and up to the present there has been very little conception of such education for its own sake, or for any other purpose than as a means to an end—the end being an academic degree which will open the way to a better position in the teaching profession than it would otherwise be possible to obtain. One would expect this to be true of the advanced classes in the training schools, but it is almost

equally the case in the Intermediate and B.A. grades of the Colleges under the University. Whereas, in England, to some extent, and in the States to a much more noticeable degree, girls go to College for the sake of the social life, or through pure interest in some special line of study; or even, in some families, as a matter of course, the situation in this country is as yet more nearly akin to that of Germany or Switzerland, where the woman student is still in some degree a *rara avis*, therefore more or less conscious of herself, her position, and the serious phases of collegiate life. . . . The higher education of women in this country has an immediate and a present interest, not only because of what has been and is, but also because of the real need that exists, and because of the unlimited possibilities of future development.

MANUAL WORK IN SECONDARY SCHOOLS.

The following memorandum has been issued by the Board of Education, Whitehall:—

For the ordinary course under Section 4 of the Regulations, the Board have not laid down any strict definition of the nature of the manual work for which provision is to be made, nor have they prescribed the amount of time that should be given to it. While, therefore, a large discretion is left to schools in the matter, it is desirable to indicate what kind and amount of work will be regarded as normally satisfying the requirements of this Regulation.

The object of the Board is to ensure that scholars passing through the course receive some definite and systematic instruction of a progressive kind which will train them to observe accurately, to use their fingers skilfully, and to exercise forethought and intelligence in the use of means towards definite ends in production.

In a school where there are classes below those taking the course, provision will already have been made in these classes, in accordance with Section 2 of the Regulations, for work to develop accuracy of observation and skill of hand. For this purpose no special work-room or elaborate apparatus is needed. Among suitable subjects may be named plaiting and weaving (for quite young children), basket work, modelling in clay or plasticine, and cardboard work in connection with geometrical drawing.

For scholars in the course this kind of instruction ought to be further developed. For boys a course in wood-work (and, where this can conveniently be added, in metal-work also) is educationally the most useful. Any course in wood or metal-work ought to be thorough. True and accurate work is absolutely essential for the object in view, and this cannot be secured without a bench and proper tools. Slovenly teaching must, above all things, be avoided. Knowledge of and skill in the use of a few good tools is essential. A workshop fitted with benches and sufficient apparatus is desirable in all well-equipped schools. Almost any room that is well lighted and sufficiently warmed and ventilated may be used for this purpose. The general indirect educational value of doing work under orderly conditions and with proper equipment is very great. But this special provision will not be insisted upon in all cases, and the Board will have regard to the circumstances of each school in determining what kind of provision short of this it may be reasonably required to make. Of the other subjects named above, clay modelling in connection with plenty of free drawing is probably the best suited for scholars over twelve. It is equally applicable to boys and girls.

It is not required that manual work shall form part of the instruction in each term or even in each year of the course. It may often be desirable to take it for only one term in the school-year, and to give more time and attention to it then. Such an arrangement, with careful planning of hours, will enable even a small workshop to be used by large numbers of scholars in the course of the year. It will also allow of the instruction being given in periods of sufficient length. For wood or iron-work in particular, a period of two hours, including the time given to the preliminary drawings, is found to be necessary in order to produce the best educational results. With such a period, taken once a week throughout a term, good and solid progress can be made. For other kinds of manual work shorter periods may be found sufficient. In all cases the educational value of the work is largely increased by its being so arranged as to require some continuous and concentrated effort from the scholars.

For girls it is provided that the course shall include instruction in practical housewifery with or without other manual work. Some kinds of needlework, with the subsidiary processes of designing, cutting-out, &c., give good training to both hand and eye; and the same is true of most other instruction which comes under the head of Practical Housewifery, if planned with special regard to that end. Gardening, for both boys and girls, where facilities for it exist, also gives this training together with healthy out-of-door exercise.

In all these cases it should be borne in mind that the training sought is of a practical as well as an intellectual and moral nature, and that the work done should therefore not confine itself to exercises in method, but should be directed concurrently, and almost from the first, towards the production of actual things. It should also be understood that the subjects mentioned here do not profess to be an exhaustive list of the kinds of Manual Work suitable for Secondary Schools. Any well-planned course of progressive instruction which, in the opinion of the School Authorities, will carry out the general object aimed at may be submitted for approval, and will not be disallowed unless it clearly fails, through insufficient amount or inferior quality, to meet the object which, as stated above, the Board have in view in the Regulation.

HOME INDUSTRIES.

Mother-of-Pearl Buttons.—How trade may be lost, or diverted, is shown by what has befallen mother-of-pearl shell. Twenty years ago Tahiti black-edged shells fetched a comparatively small price in London. Then prices augmented and remained fairly firm at renumerative rates until 1903 when best, clean, sound shells fetched as much as £200 to £220 per ton, whilst second and third grades brought about £160 and £110 respectively. For ten years previous to 1903 the annual export of shell from Tahiti had averaged about 400 tons, the yearly output varying from 550 to 290 tons according to the productiveness of the lagoons open to divers. To all appearance, therefore, the demand for Tahitian shells had become steady. Then came a revolving storm of great violence causing heavy seas to sweep over certain of the low-lying atolls of the Paumoto group. Exaggerated descriptions of the catastrophe, and of the assured destruction of the shell beds, were immediately put into circulation, with the result that holders of shell in London raised prices, and, thereupon, in anticipation of a future dearth of black-edged shells in consequence of the disaster, button manufacturers, and those responsible for the fashions in dress, decided to change the mode from buttons of mother-of-pearl to those of metal, or of other suitable material. Meanwhile the authorities at Tahiti stimulated the output of shells at the Paumoto Islands by throwing open most of the best lagoons in that region, and by sanctioning the employment of diving machines, with the result that 660 tons of shell were exported in 1904, an over-production which, combined with the decreased demand following the change in fashions, has diminished the price of Tahitian shells in the London market to practically one-half what it was three years ago. Mr. Consul Simons, from whose report (No. 3493, Annual Series) the above figures are taken, says that the authorities at Tahiti stopped all diving operations at the shell islands from October 1, 1904, to February 1, 1905, and extended this prohibition to diving machines to May 1, 1905, precautions that should restrain within reasonable bounds the output for 1905.

Motor Omnibuses.—In their report on the means of locomotion and transport in London the Royal Commission, recently sitting, expressed the opinion that whilst motor 'buses are likely to practically supersede horse omnibuses, "and thus remove from the streets, greatly to the public advantage, a form of vehicle which, although it has been of great public utility, is now one of the principal causes of congestion in many streets," tramways will continue to be the most efficient and cheapest means of street conveyance. However that may be the motor omnibuses are making rapid headway. Three new motor omnibuses are being delivered to the London Motor Omnibus Company every week; the London General Omnibus Company have commenced a new service from Cricklewood to the Law Courts; other companies are opening up other routes, and now the experiment of a motor service to Brighton has began. The journey of fifty miles is to take something less than four hours, and it is expected that what may be called the intermediate service will be a very profitable part of the undertaking. It is too soon as yet to say whether the motor omnibuses can compete successfully for long distances with the railways, but that they will have an immense and beneficial effect in pushing residential London further into the country can hardly be doubted.

The Hop Crop.—Reference was made in the last number of the *Journal* to the acreage in hops over a series of years to 1904. The preliminary statement for the year 1905 of the Agricultural Returns of Great Britain has since been published, and shows that the acreage under hops this year is slightly in excess of that of 1904—48,968 acres as against 47,799 acres last year, an increase of 1,169 acres. The only hop-growing counties that do not show an increase in acreage under cultivation this year are Surrey and Salop, but the decrease is insignificant, in the one case 34 acres and in the other 5. The hop crop of the present year promises to be one of the largest of recent years, but the low temperature and wet weather of last week may have injured to some extent the quality. As was pointed out in the last issue of the *Journal*, the fluctuation in the yield of hops is very great, and the acreage under cultivation gives little indication of the quantity of hops produced. It is stated on authority that, so far as the English crop is concerned, there is not a bad district this year, and that there will be sufficient for all requirements without any importations.

Agriculture in Scotland.—In *The Times* of August 29th there is an interesting letter from Mr. J. Boyd Kinnear on the exodus from the country side. Mr. Kinnear says it is not visible across the border. There the labourers are content with village life because they are paid and housed well, and farmers thrive because they are given a free hand and treated fairly by their landlords. Without touching upon controversial matter it may be said that the wages of labourers are generally good north of the Tweed, but when Mr. Kinnear says that "speaking generally the rates are about 20s. a week with free cottage and garden," he does not quite agree with the official figures as found in the Abstract of Labour Statistics of the United Kingdom, 1902-1904 (Cd. 2491) In this return the average wages in every county of Scotland is given, and the highest wages paid in cash, not to ordinary labourers, but to shepherds, is 18s. 6d. in Linlithgow, the next being 17s. 11d. in Haddington. In Berwick the shepherds cash wage is only 14s. 4d., but allowances in kind bring it up to 21s. 7d. The highest wages paid in the United Kingdom to the ordinary labourer are in Northumberland and Durham, where he gets in the one county 19s. 4d. in

cash and allowances in kind that bring it up to 21s. 7d., and in the other 20s. in cash, with allowances bringing it up to 22s. 2d.

The Growth of Grass Land.—Mr. Kinnear goes on to say that "south of Northumberland the traveller sees rare fields of corn or roots, but field after field of grass (mostly poor) showing by its ridge and furrows that it had once been grain. To the north of that line the picture is reversed. With stretches of waving corn or yellow stubble (much of it wheat), broken by the vivid green of turnips and swedes, with but an occasional enclosure of pasture." Here again the official figures hardly bear out Mr. Kinnear's description in its entirety. Turning to the Agricultural Statistics 1904 (Cd. 2504), it will be found that whilst the acreage under wheat in England has decreased some 55 per cent. since the agricultural position was at its best in the seventies, the shrinkage n Scotland has been 65 per cent. The decrease in swedes and turnips has been much less in Scotland than in England—about 10 per cent, as compared with 30—but the increase in grass land has been in both countries about 30 per cent. Of course in some counties the change is more marked than in others, but in all the official returns show it to have been very considerable.

The Bacon and Ham Industry.—The threatened dearness of bacon, consequent largely upon the shrinkage of imports from Denmark, and in a lesser degree from Ireland, invites inquiry as to why more pigs are not reared in the United Kingdom. Whilst population continues to increase, not so rapidly as in the past but still rapidly, the number of pigs in Great Britain is actually less than it was ten years ago. In 1895 the number was 2,884,431; the returns just published put the number for 1904 at 2,861,644. In the meantime, the price of imported bacon, although fluctuating rather widely, has on the whole increased. In 1895 it was at an average of 39·01 shillings per cwt., in 1904 it was 47·07. Now it is very much higher. The price of Irish, Wiltshire, and Danish green bacon, which in January was at 56s. per cwt., is now quoted at 74s. In Ireland as in England, the number of pigs has decreased. In 1904 they numbered 2,861,644, and this year only 2,424,919, whilst the imports of pigs from Ireland to this country which in 1900 amounted to 715,202, fell last year to 505,080, and may be expected to be much smaller in 1905. On the other hand the imports of bacon from abroad show unbroken growth during the last fifteen years. In 1890 the value of the bacon imported into the United Kingdom was £6,978,061, and of hams £2,869,115; in 1904 the value of the one import had risen to £12,832,142, and the other to £3,104,999, so that at the present time the country is buying bacon and ham from abroad to the value, in round figures, of £16,000,000 per annum. It seems strange that under these circumstances the supply of pigs in the United Kingdom instead of increasing largely should show diminution as compared with the numbers of ten years ago.

Butter, Cheese, Eggs.—It is the same with butter and margarine, with cheese, lard, eggs. The acreage under grass in the United Kingdom has increased from 26,698,739 acres in 1889 to 28,693,305 in 1904, and it might have been expected that the home population would have been less dependent than in the past upon importation of these food articles. But the value of the butter imported has risen from £8,010,374 in 1887 to £21,117,162 in 1904; of cheese from £4,514,382 to £5,843,770; of condensed milk from £734,676 to £1,608,391; of eggs from £3,085,681 to £6,730,574; of lard from £1,604,243 to £3,342,389. Of course, population has increased considerably over this period of years, but if the proportional quantities per head of the population of the articles so imported are taken, it will be fouud that in most cases the proportion has steadily grown. For example, in 1887 the butter and margarine imported represented 8·5 lbs. per head of the population, in 1904 it had increased to 13·6, the proportion of foreign cheese consumed had increased from 5·6 lbs. to 6·7 per head, of lard from 2·8 to 4·8, and the number of eggs from 30 to 56.

The Rating of Machinery.—Reference was recently made in the *Journal* to the question of the rating of machinery, and since then the London Machinery League has prepared a statement that may be useful for reference. There can be no doubt that the Act of 1840 was intended to exempt machinery not attached to a building from being rated. That is admitted on all sides, and as the Act of 1840 is renewed every year by Parliament, it would seem reasonable to ask Parliament to give effect to its own Act. The present variation in the practice of the local authorities in construing the Act is due to contradictory judicial decisions, but it is obviously desirable that all districts should be treated alike, which is not the case at present. For example, Westminster does not tax machinery attached to the hereditament; Southwark and West Ham do, Manchester and Oldham do not, Newcastle does. This inequality of treatment was condemned by the Royal Commission of 1901, and would not be defended even by local authorities who consider that they are justified in rating.

Deep Sea Fishing.—Reference was recently made in the *Journal* to the growing consumption of fish in Germany, which is likely to be stimulated this year by the high price of meat. The German Government stimulates and protects the fishing industry in many ways. For example, all subventions for the building of new sailing vessels and for providing them with outfits of nets and gear, as well as all loans to fishermen and fishing companies, are made by the Government through the German Sea Fishing Association upon the representation of the latter. On such matters, as well as on research and kindred

objects, the Government expends annually about £20,000 for the benefit and encouragement of sea fishing, in addition to some £2,500 or £3,000 per annum towards the expenses of the Association. The owners of new smacks to be employed in herring fishing receive a building subvention of approximately £200 to £250, besides a further sum for the purchase of nets and gear; and although steamers receive no such subventions, those engaged in herring fishing are, nevertheless, furnished by the Government with a reserve fund for making good losses in nets, which fund cannot, however, be drawn upon without the Government sanction. This reserve fund is for steamers £240, and for sailing vessels £97. In order to make good the exceptionally heavy losses in nets and gear during 1904 the Government will, it is said, contribute £5,000, in addition to the £20,000 referred to above. A fishing museum was two years ago set up in the new municipal museum at Altona, and is already so great a success that it is to be considerably enlarged and improved, the Government contributing liberally to the funds for the purchase of models, &c. In November last year the Association offered to furnish German fishermen with good, reliable barometers at 2s. 6d. each. In three months 475 of the barometers had been issued, and, the reports upon them have everywhere been favourable.

OBITUARY.

GEORGE ATHELSTANE THRUPP.—Mr. Thrupp, the well-known coach-builder, and writer on coach-building, died on the 24th ult., at his house in Maida-vale, in his 84th year. He had been a Member of the Society of Arts since 1875, and in December 1876, he delivered a course of Cantor Lectures on the "History of the Art of Coach-building," which formed the groundwork of his subsequently published work on "The History of Coaches." He was also a frequent contributor to the *Journal* on subjects connected with carriage building and technical education. Mr. Thrupp was a past master of the Coach and Harness Makers' Company, and was founder of the Coachmakers' Benevolent Institution, of the Institute of British Carriage Manufacturers, and of Technical Schools for Coach Artisans. His business in Oxford-street was founded as far back as 1740.

GENERAL NOTES.

CAPETOWN PHOTOGRAPHIC EXHIBITION.—The Capetown Photographic Society will hold an exhibition at the City Hall, Cape Town, from Saturday, February 3rd, to Saturday, February 10th (inclusive). Entries close January 13th, 1906. Communications should be addressed to A. J. Fuller, Secretary, P.O., Box 470, Cape Town.

ROYAL SANITARY INSTITUTE.—The 40th course of lectures and demonstrations for sanitary officers arranged by the Sanitary Institute will commence on September 23rd, and continue until November 29th. The course comprises four lectures on elementary physics and chemistry in relation to water, soil, air and ventilation, and meteorology; and twenty-one lectures on public health statutes, the practical duties of a sanitary inspector, municipal hygiene or hygiene of communities, and building construction in its sanitary relations. Inspections and demonstrations are arranged in connection with the lectures, and include visits to public and private works illustrative of sanitary practice and administration. In the second part, seven lectures will be given on meat and food inspection. Further particulars can be obtained from the Secretary of the Institute, Margaret-street, W.

COTTON IN ST. VINCENT.—In his report upon the affairs of St. Vincent, dated 31st January, 1905 (Cd. 2238-23), the Administrator, Mr. Edward J. Cameron, speaks very favourably of the outlook for cotton cultivation in the island. The great agricultural feature of the year, he writes, has been the inauguration of the Sea Island cotton industry under the auspices and by the very active effort of the Imperial Department of Agriculture, under Sir David Morris, K.C.M.G. The results are certainly encouraging, "136 bales of excellent cotton realising from 4d. (this figure is for the upland quality) to 1s. 3½d. per lb. have been shipped from the colony since April last, and the present area in cultivation, from which the crop is being taken off at the time of writing, is approximately 1,471 acres. With these prices, which, moreover, leave a fair margin for a fall, the industry should certainly pay, and go some way in assisting to restore the colony's shattered prosperity." It is largely a question of price and labour.

SCHOOLS IN SAXONY.—In his report on the trade of Chemnitz and Saxony (No. 3342, Annual Series), Mr. Vice-Consul Felkin gives some interesting figures bearing upon education. In 1904 there were 739,076 school children in Saxony, 360,909 boys and 378,167 girls. The number was composed of 714,395 Lutherans, 21,163 Roman Catholics, and 3,518 other religions. For these, there were 12,196 teachers, making an average of 60 pupils to one teacher, but the rate varies considerably in different sections, being as much as 80 pupils to one teacher in some districts of Chemnitz and Zwickau, and as low as 40 in some districts of Dresden and Leipzic. The expenditure for national schools amounted to £1,715,000, which represents an average of £2 6s. for each pupil of the national schools. This compares with other parts of the Empire as follows: Berlin (average), £4 15s.; Austria, £2 8s.; Bavaria, £2 6s.; Mecklenburg-Strelitz, £1 13s.; Lippe-Detmold, £1 5s. It is interesting to note that the average age at which Saxon school teachers die is 46—a figure to which it has steadily declined since 1901, when the average age was 50.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

TELEPHONY.

BY HERBERT LAWS WEBB.

Lecture I.—Delivered March 13th, 1905.

TELEPHONE INSTRUMENTS.

In attempting to cover in a course of four lectures a subject so full of technical detail as telephony, I realise that I am attempting a difficult task. Especially have I realised this during the past few weeks, when I have been engaged in extracting from a mass of information those points which I think would most interest an audience not composed wholly of telephone workers. Since one could give a paper or a lecture on any one of a thousand details in telephone engineering, I have been compelled to pick and choose, to eliminate and compress—making tabloids out of cart-loads.

I have divided the subject into the divisions which those engaged in the telephone business habitually apply. We divide a telephone system into three main parts—the equipment of the subscribers' stations, or the sub-station plant, the conduits, cables and wires joining those stations to the exchange, or the line plant, and the exchange switchboards and accessory appliances, or central office plant. I am devoting a lecture to each of these branches of the modern telephone system and one to the commercial side of the industry, the important questions of development and tariffs.

Let us take a brief glance at the rise and present position of the telephone business. The first commercial telephone exchange appeared in 1878—less than 27 years ago. At the present time there are not less than 5,000,000 telephones in use, probably, since exact statistics are difficult to collect, considerably over that figure; and at a moderate computation the telephone industry gives employment directly and indirectly to not less than a quarter of a million people. It draws on every branch of the electrical business, as, besides the many special appliances required, it needs conduits, cables, and wires in great variety, batteries, accumulators, dynamos and motors, and a host of general mechanical and electrical supplies. It also gives employment to a large number of general trades.

In scientific progress the development of telephony has been prodigious. Both the range and the scope of the telephone have enormously increased. In the early days the range of the telephone for commercial talking was a few miles. In the eighties telephone circuits of over a hundred miles were rare. To-day most of the capitals of continental Europe have direct telephonic intercommunication. In America, commercial talking is now done over distances of 2,000 miles. Ten years ago a city telephone system serving 10,000 telephones was the exception, and there were very few which exceeded that. To-day there are city telephone systems serving from 100,000 to 150,000 telephones. And so advanced are the methods of operating and the apparatus employed, that any two stations among those vast groups of telephones are put in communication with each other in an average time of about 30 seconds.

In volume of business done the telephone has long out-distanced the telegraph and is fast catching up the penny post. In this country the annual number of telephone communications is more than ten times the number of telegrams, and in America it is more than thirty times. In both countries the annual number of telephone calls is rapidly approaching the annual number of letters. Doubtless the telegraph will long continue to be used for very long distance messages and for messages where rapidity of communication is not important. But the speed, the directness and the completeness of the telephone message are so superlative that if everybody had the

telephone service, and knew how to use it, very few would send telegrams, and nobody would send a local telegram.

The Problem.

Let us for one moment go back to the dark ages, what I might call the *ante-Bellum* period, when the telephone spoke not for itself, but was only talked of. I hardly need to tell an audience like this that sounds as we know them have three distinct characteristics—pitch, or rate of vibration, loudness, or amplitude of vibration, and quality, or timbre, which is not so easy to define as it is to recognise. We habitually speak of sound vibrations as sound waves and represent them diagrammatically in wave form. The actual transmission of sounds through the air is by a to and fro vibration of the air particles, an alternate condensation and rarefaction. A simple note produces a rhythmical vibration, and if the loudness of the note increases or decreases the vibrations vary in amplitude, but not in rate, and, therefore, not in their general form. If quality is introduced, however, the form of the sound wave is modified, as quality is represented by extra vibrations, called overtones or partials, superimposed on the main vibrations. Quality is present in all sounds, and is what gives to musical sounds and to human voices their special characteristics, agreeable and otherwise. In musical instruments quality largely depends on the materials employed and the shape of the instrument. For example, we know that the same note on a piano or on a violin or on a clarionet has quite different sounds. Quality is pre-eminently present in the human voice. The variety among human voices is as great as the variety among human features, and different voices are as easily recognisable as different faces. We all carry voices in our memory, and know how easy it is to recognise with certainty a given voice at a distance. This great variety comes mainly from quality. Each voice has its own fundamental note, but it is quality, the overtones, from which such innumerable shades of sound result. Articulate speech is produced by the vibration of the vocal chords, and the quality is dependent on the tension on the chords and on the shape of the mouth cavity. By the tension we put on our vocal chords and by the movements we give to our tongue, teeth and lips, thus altering the shape of the mouth cavity or resonating chamber, we constantly vary the pitch and quality of the sounds we utter. It is an important feature of articulate speech, and one of great practical importance in telephony, that the clearness of speech does not in the least depend upon loudness, but solely upon pitch and quality. It is a common delusion, for example, that if one is not understood one must shout, and the Englishman abroad thinks to make himself understood by talking loudly in English. On the other hand we know that two people close together can converse in whispers, which shows plainly that clearness is not dependent on loudness, and not even so much on pitch as on quality.

Quality being the notable characteristic of the human voice, and quality introducing into sound vibrations innumerable extra vibrations, due to the partials or overtones, it follows that the sound waves of articulate speech are extremely complex in character. A simple note gives regular vibrations, while the sound waves due to articulate speech contain innumerable superimposed waves. The little superimposed waves are often at the rate of thousands per second.

This brief sketch of the acoustics of telephony shows us that the problem of the electrical transmission of speech was to transmit electrical waves identical in form with the sound waves. Every tiny wave must be reproduced, or the overtones, the all-important quality, would be lost, and the result would be only noises, not speech. The early thinkers and experimenters in telephony failed to recognise this vital principle. Borseul, in 1854, made a forecast of electric telephony, and described means for effecting it. But he apparently made no experiments, and his description speaks of making and breaking the current. By an interrupted current you can transmit pitch, but not quality; noises and notes, but not articulate speech.

Let us look for a moment at the means in the human system for receiving sounds, and see what guidance they give in telephony.

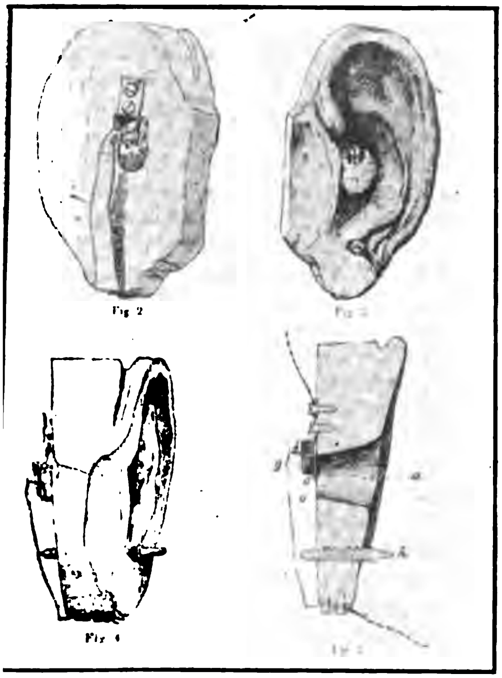
The human ear consists of an external ear, acting as a collector and resonating chamber, closed by a membrane or vibrating diaphragm to which is connected a chain of small bones, the mallet, anvil and stirrup. This chain of small bones forms an elastic system through which the vibrations taken up by the membrane from the surrounding air are transmitted to the labyrinth of auditory nerves, which convey them to the brain.

It was only natural that those who attempted to solve the problem of transmitting speech by electricity should study the mechanism of

the human ear and attempt to reproduce it. The human ear is clearly a transmitter or converter of sound waves into nerve impulses, and an electrical apparatus built on the same lines might transform sound vibrations into electrical impulses.

This was clearly the idea of Philip Reis, of Friedrichsdorf, who in the early sixties experimented extensively in electric telephony. In the early instruments of Reis are reproduced the membrane or vibrating diaphragm, the mallet and the anvil of the ear, the mallet and the anvil being interposed in the electric circuit.

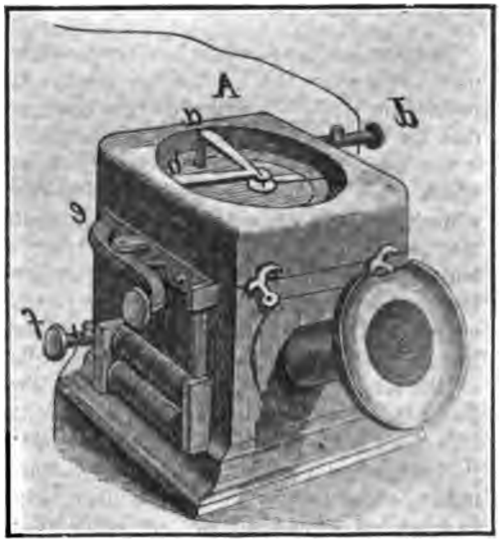
FIG. 1.



EARLY FORMS OF REIS TRANSMITTER.

Reis experimented for several years in telephony, but reached no definite results in the transmission of articulate speech, though the most finished form of his transmitter was of a type very similar to that of subsequent practical telephone transmitters. The fundamental difficulty with the Reis transmitter was that it was intended to make and break the circuit by the vibrations of the diaphragm. With a make and break transmitter the electrical waves change abruptly and do not follow the vibrations produced by articulate speech. With our present knowledge it is no difficult matter to make a Reis transmitter talk fairly well. Apparently Reis never made them talk more than a word or two at a time.

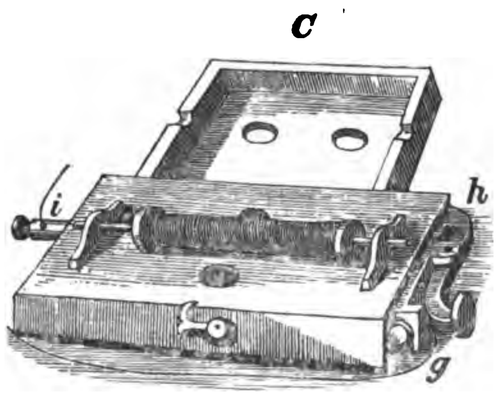
FIG. 2.



FINISHED FORM OF REIS TRANSMITTER.

The Reis receiver depended on the well-known Page effect, so-called because Professor Page, of Salem, discovered that a piece of iron, on being rapidly magnetised and demagnetised, gave out a sound. It is curious that Reis did not realise the necessity of using a diaphragm in his receivers; but all

FIG. 3.



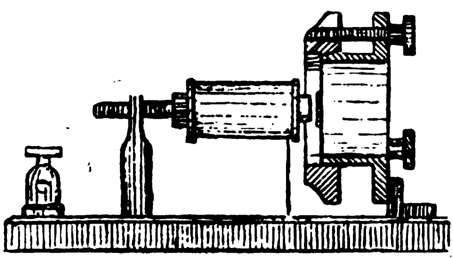
REIS RECEIVER.

his receivers were of this same form, a slender core surrounded by a coil. It seems probable that if Reis had equipped his receiver with a diaphragm he would have obtained results

which would have led to the discovery of the weak point of the transmitter, and enabled him to solve the problem. The experiments of Reis lasted seven or eight years but were never carried to a definite conclusion. In the early seventies Reis became an invalid and he died in 1874.

There was a lapse in telephonic experiments until Professor Bell definitely solved the problem in 1876. To Bell is due the discovery that for the transmission of articulate speech it was necessary to use an undulatory current which should exactly reproduce the voice vibrations. The means for doing this—the magnet, the coil and the iron diaphragm—had lain under the hands of all experimenters in electricity since the invention of the electro-magnet. The attainment of such great ends by such simple means has well been described as the very "hardihood of invention." Professor Bell thus described his discovery in the fifth claim of his patent of March 7th, 1876:—"The method of and apparatus for transmitting vocal sounds telegraphically, as herein described, *by causing electric undulations similar in form to the vibrations of the air* accompanying the said vocal or other sounds substantially as set forth."

FIG. 4.



EARLY BELL TELEPHONE.

In the earliest form of practical telephone transmitter devised by Bell the diaphragm was of membrane with a piece of iron attached to it at the centre. The iron armature, being vibrated by the diaphragm in front of the magnet poles, set up undulatory currents in the coils, which, circulating in the receiver coils, varied the magnetism of the receiver magnet, and vibrated the receiver diaphragm correspondingly. This simple apparatus transmitted articulate speech electrically, founded a new art, and gave rise to a new industry.

In the earliest telephone circuits magnet telephones were used both for transmitters and receivers. At first an electro-magnet was used in the transmitter, but this soon gave way to a permanent magnet; and the membrane diaphragm, which got slack in damp weather, was replaced by an iron diaphragm. The earliest form of receiver was a cylindrical iron box containing the magnet within and closed by the diaphragm.

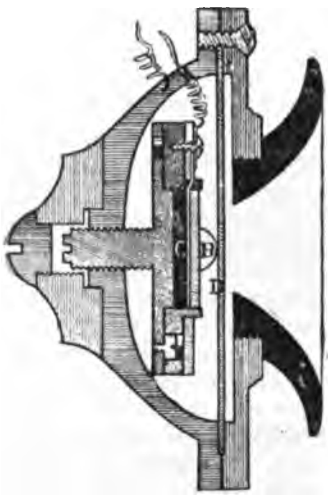
The late Professor Elisha Gray, the inventor of the harmonic telegraph and of the telautograph, was working at the telephone at the same time as Bell. Gray undoubtedly experimented with a continuous circuit, with undulatory currents, and even with a battery transmitter.

Gray ran a very close race with Bell for the glorious invention of the telephone; indeed a preliminary patent application, or *caveat*, was lodged by each on the same day. But Bell secured priority for his invention and is universally recognised as the real inventor of the telephone. The insight which Gray had into the problem is shown by one of his patent drawings, in which we have a complete telephone circuit, with battery transmitter and magnet receiver. The variable resistance of the transmitter was a platinum wire dipping into a liquid. The variation of resistance due to the up and down movement of the platinum wire as it was vibrated by the diaphragm would be extremely small; still, the principle of the modern transmitter—an unbroken contact—was there.

We have skimmed rapidly over the underlying principles and we now come to the era of practical telephony—which began in 1877. The first complete telephone circuits used magnet telephones as both transmitters and receivers. The magnet telephone as a transmitter is practically a small dynamo, the prime mover being the human voice—a comparatively feeble source of energy. Although it is surprising how far and how well one can talk with a well-constructed magnet telephone and over a good line, still it was clear in the early days of telephony—when neither the apparatus nor the lines were very efficient—that to give the telephone sufficient range to make it of commercial value, a more powerful form of transmitter was required. Some workers endeavoured to make the magnet telephone more powerful; others turned their attention to the production of a battery transmitter. This was first produced by Edison. Edison utilised the principle, previously announced by Du Moncel, that the resistance at a contact between two conducting substances varied with variation in pressure. Both Count du Moncel and a French

engineer named Clarac had pointed out that carbon exhibited in a marked degree the property of diminishing its resistance with increase of pressure, and Edison relied rather upon this than upon actual variation of resistance at the point of contact.

FIG. 5.



EDISON CARBON TRANSMITTER.

In the early commercial form of the Edison transmitter the variable resistance was a button of compressed lamp black held between two plates, an ivory button conveying the vibrations of the diaphragm to the front plate.

At about the same time Berliner invented a battery transmitter, which also relied upon variation of resistance through variation of pressure at a contact. Berliner made his contacts of metal.

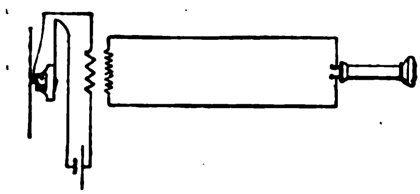
The introduction of the battery transmitter, which enabled external power to be applied to the telephone circuit, the flow of current being regulated by the changes in resistance of the transmitter due to the voice vibrations, was a notable advance in telephony. Mr. Edison at the same time made a contribution of great value to the telephone circuit by combining the transmitter with the induction coil. In the telephone circuit the induction coil becomes a sort of step-up transformer, sending out to line currents at comparatively high pressure, while the local or primary circuit is kept of low resistance, thus giving the variations in resistance of the transmitter their maximum range. This was a most valuable improvement, and the induction coil has since formed an essential part of the telephone transmitter.

In 1878, Professor Hughes explained the real principle of the telephone transmitter. By his famous microphone, by the beautiful experiments he conducted with it, and by the lucid explanation he gave of the phenomena observed, he threw a flood of light on the whole subject. He made clear that, for the maximum effect in change of resistance with change of pressure, the essential point was a loose contact.

Edison had worked with exactly opposite means, a compressed button held closely between two plates. Although there was a controversy at the time as to the invention of the carbon transmitter, it has long ago been recognised that Hughes was the first to demonstrate the correct principles on which telephone transmitters should be built, and since 1878 all transmitters have been built around the loose contact.

We now have the complete telephone circuit invented; the battery transmitter with induction coil, the magnet telephone taking its place as receiver.

FIG. 6.



COMPLETE TELEPHONE CIRCUIT; BATTERY TRANSMITTER, INDUCTION COIL AND RECEIVER.

It is worthy of note that within a year of the production of the first speaking telephone, which spoke at first in rather feeble and hesitating tones, the art of telephony had reached this advanced stage, in which we have all the essential features of the modern telephone circuit.

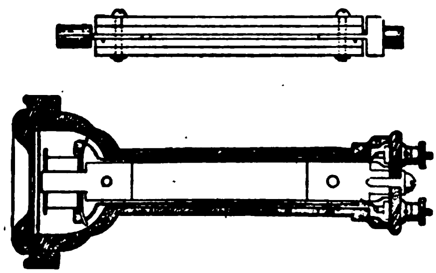
We may now consider the evolution of the magnet telephone as a receiver, which has been its function since 1878.

After passing through a few stages of somewhat crude mechanical design and arrangement (examples of early wood-case receivers were exhibited on the lecture table) the receiver took the form shown in Fig. 7.

The essential features are the laminated magnet, giving superior strength and permanence of magnetism as compared with a solid magnet, the soft iron pole-piece, the ebonite case, the small air chamber and the

shallow ear-piece. This is a receiver of about 1880, and it shows careful study of both the electro-magnetic and acoustic requirements of the receiver. The function of the currents circulating in the coil is to produce changes in the magnetic field in which the diaphragm is placed. Soft iron is more responsive to changes in magnetisation than steel, so the soft iron core quickly found its way to the top of the telephone magnet and has remained there ever since. Only for a year or two were receivers made with the coil mounted directly on the magnet. Acoustically, also, this receiver shows considerable advance on its immediate predecessor. We know that a resonating chamber—any column of air, in fact—has more or less effect on the quality of sounds, reinforcing some notes or vibrations to

Fig. 7.



Single Pole Receiver.

the detriment of others. This is familiar in the difference in the sound of voices in an empty room and in one that is furnished, or in the different sound given to a voice by speaking near or over a hollow vessel. The early wood-case receivers had large air chambers and deep ear-pieces, thus furnishing resonators which considerably distorted the sounds received. This trouble was cured by using the extremely small air-chamber and shallow ear-piece shown in Fig. 7, with a marked improvement in the quality of speech received.

In the early days many attempts were made to improve the magnet telephone by strengthening the magnetic field, by using two diaphragms, by employing clusters of magnets, by connecting magnetically the diaphragm with the magnet and by various combinations of the simple parts of which the instrument consists.

The late George M. Phelps, who worked assiduously in the commercial development of the telephone in its early days produced many types of instrument having combinations of several magnets.

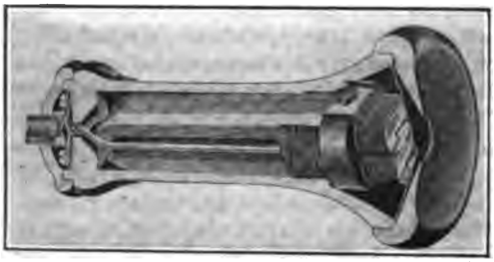
European investigators appear to have endeavoured to improve the magnetic circuit of the telephone. Among the many scores of receivers made in all shapes and forms in the early days of telephony, practically none has survived. That of Mr. Ader was the most interesting and the most practical. This was a double-pole receiver with a ring of soft iron placed in the ear-piece above the diaphragm. This iron ring Mr. Ader called a "super-exciter" and it is clear that the diaphragm is thus placed in a stronger magnetic field.

The evolution of the receiver has proceeded along the systematic lines of improvement in magnetic, mechanical, and acoustic details. The single-pole was some ten years ago replaced by the double-pole magnet, which was of superior power and sensitiveness, and at the same time resulted in a smaller and handier instrument. The diaphragm has practically not changed at all. It is of soft iron, a little over two inches in diameter and ·01 inch thick, either japanned or tinned to prevent rust. Many experiments have been made with diaphragms of varying thicknesses. It has been found that with thick diaphragms some of the higher overtones are lost, and the talking becomes thick and hoarse. With thin diaphragms the talking is sharp and clear, becoming shrill as the diaphragm diminishes in thickness. A very thin diaphragm tends to become pulled down on the pole piece, and general experience has settled on a thickness of ·01 inch. The diaphragm is placed as near to the pole pieces as it can be placed without risk of it being pulled into contact with the pole-pieces, the air-gap is usually 1-32nd of an inch, and the space between the diaphragm and the ear-piece the same. The ear-piece has become shallower, and the orifice smaller. The sensitiveness of the receiver depends upon the magnetic circuit being in a state of unstable magnetic equilibrium, so to speak. The permeability of the diaphragm must be high, and the field in which it is placed be concentrated, so that changes in the distribution of the lines of force caused by the currents circulating in the coil shall have the maximum effect. Great study is now made of the magnetic properties of the irons and steels used in telephone receivers, as the constant increase in the range of talking required constantly increases the demand on the power and sensitiveness of the receiver.

In mechanical design the telephone receiver

has been greatly improved. In the early single-pole receivers the magnet was attached to the rear end of the case. Unequal expansion often made the receiver useless by taking the diaphragm too near the magnet or too far away from it. It is now the practice to attach the magnet to the case at the shoulder. In the type shown in Fig. 8, a brass block is screwed

FIG. 8.



DOUBLE POLE RECEIVER.

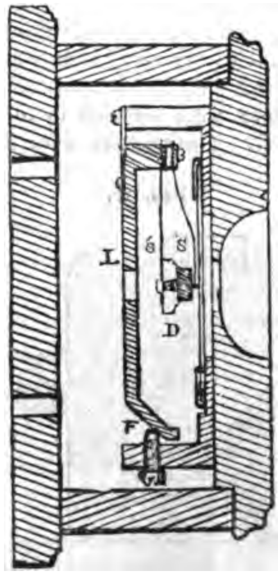
into the case. The cord is now frequently carried within the case instead of being attached to exposed terminals. Sometimes a metal case is used with ebonite covering. The telephone receiver has to stand much hard usage, and it must be proof against it.

EVOLUTION ON THE TRANSMITTER.

The earliest form of commercial transmitter was the well-known Blake instrument, Fig. 9, which was at one time extensively in use in England and America. Blake utilised the loose contact of Hughes and the carbon button of Edison, giving the rear electrode inertia by mounting it on a metal backing. The two electrodes, the front one a platinum point, were mounted on springs, so that they might follow all the motions of the diaphragm. An ingenious adjusting device, consisting of an angular iron bracket, to which the springs were attached, held under tension by an adjusting screw, was provided to maintain the two electrodes in constant contact. The Blake transmitter (Fig. 9), with one cell of Leclanché battery, and when everything was in proper condition, gave very clear talking over lines of moderate length; but it would not stand a high battery power, and it required frequent attention and adjustment. The adjustment was rather a delicate matter; frequently a a quarter-turn of the screw made all the difference between good talking and bad.

In Europe, after Professor Hughes published his famous paper on the microphone, many commercial transmitters were designed which were simply variations of Hughes's carbon pencil microphone. A large family of transmitters sprang up, in which carbon pencils were arranged in every conceivable manner, in single and double rows, in stars, in wheels,

FIG. 9.



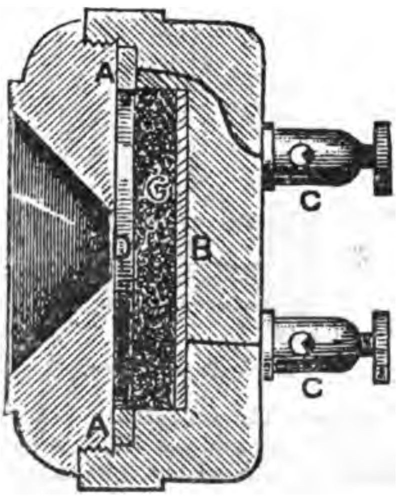
BLAKE TRANSMITTER.

in hexagons. These assemblies of blocks and pencils were generally attached to wooden diaphragms. The quality of talking from a microphone transmitter is very variable, as the instrument is very sensitive to jarring, and with strong battery power hissing and frying frequently occur, due to minute arcs at the contacts. Except in one or two countries the microphone transmitter has dropped out of use.

The Hunnings transmitter, of which Fig. 10 shows an early form, is the father of all modern transmitters. The granular carbon transmitters were invented by the Rev. Henry Hunnings, who seems to have made a meteoric flight into telephony. Even in its earliest and simplest form the granular carbon transmitter was a far more sensitive and powerful instrument than either the Blake or the carbon pencil family. It was free from the ordinary defects of both classes, the breaking, hissing, and frying, and the barrelly, hollow talking, but, unfortunately, it developed a serious defect of its own—a defect which took a long time to

overcome. This trouble has been called "packing," and for years "packing" was one of the greatest bugbears of the telephone engineer. The granular carbon transmitter came rapidly into use, as it gave clearer and louder talking than previous forms, and could be used with a higher battery power. The demand for long distance taking was constantly increasing, and a more powerful transmitter was a necessity. It was found, however, that the granular transmitter often became obstinately silent. This was attributed to the carbon granules becoming tightly packed together, so that they no longer vibrated freely. Many devices were resorted to to overcome this difficulty. Transmitters were made with

FIG. 10.



HUNNINGS TRANSMITTER.

the electrodes of irregular shape, so as to break up the granules; in some instruments the transmitter case was mounted on a pivot, so that it could be twisted round to shake up the granules when the talking became weak.

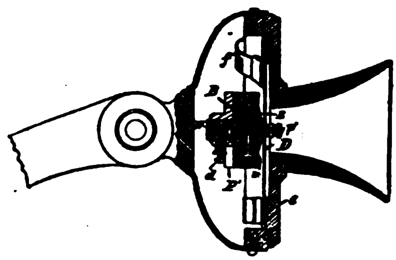
A type of granular transmitter in which special precautions were taken to prevent packing, was at one time extensively used in America, called the "long distance." It had a platinum diaphragm, set horizontally, on which the carbon granules rested, and the upper electrode was in the shape of a pulley, grooved and pierced so as to allow the granules to be well distributed. This was a powerful transmitter, and could be used with three cells of Fuller battery, giving about six volts. It gave good talking over very long lines when in good condition, but it suffered from the packing evil, and at times would become as silent as a block of solid metal.

Packing is due not merely to the carbon granules becoming settled down, but to the expansion due to heating causing the granules to swell together into a mass. In a granular transmitter the resistance is often very low, less than an ohm, and sufficient current passes to generate considerable heat. The cause of the packing trouble was therefore inherent to the instrument if a powerful transmitter was required.

A detailed investigation of this and other properties of granular transmitters, carried out at laboratories of the American Bell Telephone Company and at the Massachusetts Institute of Technology, resulted in showing that the packing trouble could be cured by giving the granules space to expand, and that the greatest effect in change of resistance from change of pressure was obtained by mounting the rear electrode rigidly.

The "solid back" transmitter (Fig. 11) was

FIG. 11.



SOLID BACK TRANSMITTER.

the result of these researches, and was designed by Mr. Anthony White about thirteen years ago. This is the most powerful telephone transmitter in use, and does daily commercial talking over distances ranging from a few yards up to 2,000 miles. The two electrodes are small discs of carbon, slightly smaller than the containing chamber. The rear electrode is attached to a brass block rigidly held by a substantial brass bridge. The front electrode is connected by a pin to the diaphragm, a washer over the same pin holding a mica disc which closes the granule containing chamber. The front electrode has a piston-like action in the chamber, the mica disc having sufficient elasticity to allow the electrode to vibrate freely. The mica is proof against the heat generated in the transmitter, which the felt ring used to give elasticity in earlier types of small granular transmitter was not. The carbon

granules only partly fill the space between the two electrodes, and thus have free space in which to expand when they become heated.

This transmitter has been successful in overcoming the packing difficulty, and when once properly set up it rarely develops faults of any sort. Its general design has been extensively copied, and, like the Hughes microphone, it is the father of a whole family of instruments.

In another family of granular transmitters, a containing chamber with elastic sides is employed. This is generally secured by the use of a ring of felt, which has caused this type of instrument to be irreverently dubbed in America the "cornplaster" transmitter. Sometimes the felt separator is simply a ring, sometimes it is a disc pierced with several holes to split up the granules more.

Great attention must be paid to the workmanship, quality of materials, and details of assembly in telephone transmitters. The preparation of the carbon granules has become quite a specialty and much care is expended on getting carbon of a high degree of hardness and fineness, practically small black diamonds. The acoustic properties of transmitters are also of importance. A small degree of distortion necessarily takes place in the transmitter, as there is a conversion of energy from one form to another. Any unnecessary addition to this distortion must be guarded against. The fundamental note of the diaphragm must be damped out, and anything in the shape of a resonating chamber which would tend to reinforce some vibrations over others must be avoided.

At various times there have been many what might be called "freak" transmitters invented, instruments with multiple contacts and multiple diaphragms. These were very frequent in the early days, when it was not realised that the line was the principal problem, not the instruments. Broadly speaking none of these devices has lived, but the double diaphragm idea has lately been revived in a commercial transmitter. This instrument has two granular chambers back to back, the two diaphragms being placed in a chamber parallel with the mouthpiece.

Signalling Appliances.

To use the telephone it is necessary to have means of signalling and of being signalled. When the telephone appeared the ordinary trembling electric bell was already in general use and it was at once pressed into the service of the telephone. It quickly became evident that the batteries required for signalling over lines of any length were expensive, unreliable, and troublesome, and the magneto call and polarised bell, not unknown but not then much used, were soon substituted for batteries and trembling bells.

The magneto generator is such a well-known appliance that it needs no description. It is simply a small hand-driven alternating current dynamo. The armature of the bell is polarised by a permanent magnet, giving it a normal bias, and so making it responsive to normal currents.

The magneto generator proved such a simple and adequate means for signalling on telephone lines, that it soon became almost universally an indispensable part of the telephone set. In the early days it was inserted in series in the line and an automatic shunt had to be devised to short-circuit the armature coil when the generator was not in use. There are various forms of automatic shunt. In one most generally used the spindle of the armature coil normally short circuits the coil by pressing against a contact, from which it is drawn when the handle is turned by the action of a pin which rides up from a notch in the hub of the driving wheel.

The telephone station must have two different positions: one for sending and receiving signals and one for sending and receiving speech. At first a hand switch was used for changing the circuit from one position to another. It was soon seen that the weight of the receiver afforded means for effecting this change automatically, and the automatic switch-hook was invented. This device plays an important function in the telephone set, and its details have received much study. In the early days the arm of the hook formed part of the circuit, and it worked between leaf contacts. There was more or less uncertainty about this, and in modern practice the contacts are separated from the hook, and are simply controlled by it.

Circuits of Telephone Sets.

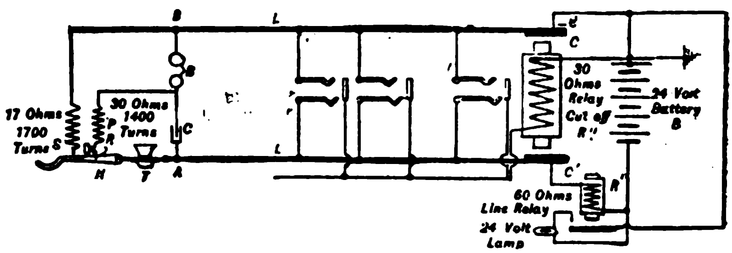
We have now surveyed the essential parts of the complete telephone set. These parts may be joined up in a variety of different ways. In the early days, when single lines with earth return were generally used, everything was joined in series.

Such a circuit has various disadvantages. The resistance of the bell coils, with that of the generator armature if the shunt contact failed, was in the talking circuit; on long lines with several stations both talking and

signalling became ineffective. Mr J. J. Carty then invented the bridging bell, which completely cured this trouble and gave a much superior circuit. In the bridging bell both the bell and the generator are in bridge across the line. The bell coils, having long cores and being wound to a high resistance, offer high impedance to telephonic currents and do not shunt them. With this arrangement practically any number of telephones may be worked on one line with good results.

Finally, we have the common battery circuit, the standard circuit of to-day, in which the arrangement of the sub-station is much simplified. The transmitter battery has disappeared, as current is supplied from the central office; the generator has disappeared, as the same central battery operates the signals at the central office. There are left only the transmitter, induction coil, receiver, and bell, and the automatic switch to change the circuit from the signalling to the talking position. There is one additional part, that inconspicuous and most serviceable electrical device—the condenser. The condenser serves to maintain the line normally "open" to direct current, but allows the polarised bell to be rung by alternating current. As may readily be seen, the various elements of a common battery sub-station circuit may be arranged in a variety of ways, and, owing to the reactions between the coil, condenser, transmitter, and receiver, different ways will give different talking results. Innumerable different arrangements of the circuits have been tried; the circuit shown in Fig. 12 is that which on the whole is found to give the best results.

FIG. 12.



CIRCUIT OF COMMON BATTERY, SUB-STATION SET.

COMPLETE TELEPHONE SETS.

Having traced the manner in which the various parts of the telephone sub-station have been evolved, I now invite you to go back to 1877 and make a rapid survey of the evolution of the complete commercial telephone set.

Not very long after the speaking telephone was shown to be a practical success commercial instruments were put on the market. The first of these was a hand magneto telephone. This was in use in 1877. It was not beautiful but appears to have been built for strength and to have been well finished. A short time later a complete telephone set was on the market, and this is specially interesting as it contained all the elements of the modern set; generator, bell, and automatic switch.

The wall set of the same period was the prototype of the wall set which has become so familiar. Here we have a separate transmitter, receiver, generator, and bell. The circuit was changed, however, from the signalling to the speaking position by a hand-switch.*

In connection with these early commercial instruments, it will no doubt be interesting to many if I quote a few lines from the first circular issued in connection with the telephone industry. It is dated Boston, May, 1877, and reads as follows:—

"The proprietors of the telephone, the invention of Alexander Graham Bell, for which patents have been issued by the United States and Great Britain, are now prepared to furnish telephones for the transmission of articulate speech through instruments not more than twenty miles apart. Conversation can be easily carried on after slight practice, and with the occasional repetition of a word or a sentence. On first listening to the telephone, though the sound is perfectly audible, the articulation seems to be indistinct; but after a few trials the ear becomes accustomed to the peculiar sound, and finds little difficulty in understanding the words.

"The telephone should be set in a quiet place,

* Illustrations of these early commercial telephones were shown at the lecture.

where there is no noise which would interrupt ordinary conversation.

"The advantages of the telephone over the telegraph for local business are:—

"1st. That no skilled operator is required, but direct communication may be had by speech without the intervention of a third person.

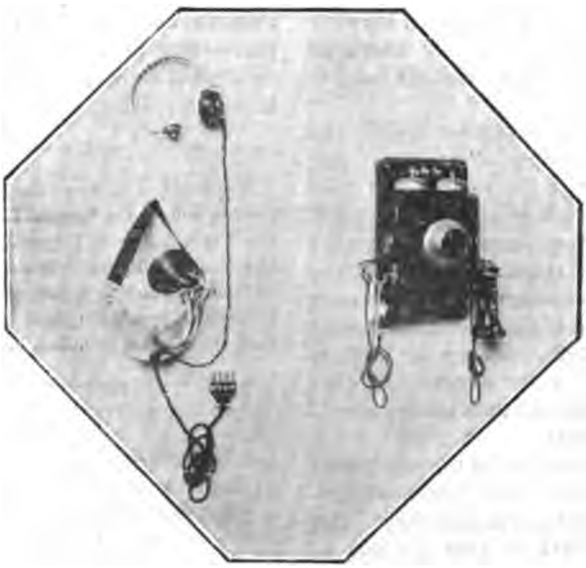
"2nd. That the communication is much more rapid, the average number of words transmitted a minute by Morse Sounder being from fifteen to twenty, by telephone from one to two hundred."

"3rd. That no expense is reported either for its operation, maintenance, or repair. It needs no battery, and has no complicated machinery. It is unsurpassed for economy and simplicity."

of the transmitter, and the absence of a rigid support are not good for long distance talking, and the instrument, as a whole, is more subject to risk of damage than when only the receiver is movable.

In the common battery set, the standard instrument of to-day, of which a wall pattern set is shown in Fig. 13, it is noticeable that the sub-station has become much more compact. The elimination of the generator and battery has eliminated much bulky cabinet work. The switch-hook offers a notable detail. It was found that people who did not "keep their eye on the ball," to use a golfing phrase,

FIG. 13.



OPERATOR'S TELEPHONE SET AND WALL PATTERN COMMON BATTERY SET.

The microtelephone or hand set, which was first used in America about 25 years ago as a switchboard instrument, has become very popular in Europe. It has its advantages and disadvantages. With a wall set it makes the position of the telephone independent of the height of the user. With a desk set it is a comfort no doubt at times to be able to sit back with the telephone instead of leaning forward to it; but the hand set involves a long cord, and the long cord hss a terrible habit of coiling itself up under a pile of papers and books, sometimes with disastrous results. Electrically, the hand set is not so good as the fixed transmitter. The long cord with its numerous conductors is a weak spot from a maintenance point of view; the shaking up frequently jabbed the receiver downward so that a point of the switch-hook dented or bent the diaphragm. This resulted in many damaged receivers, and much bad service. Even curving the ends of the prong does not cure the trouble, as many people prefer to do things upside down, and jabbed the receiver diaphragm up. So it became necessary to shape the ends of the hook in a ring of sufficient radius that it was impossible to damage the diaphragm by means of the hook. People had to choose other means. This is just an illustration of the great attention which must be paid even to the smallest detail in telephone work, and of the necessity for the telephone engineer to guard against the damage which thoughtless and careless

members of the public so quickly deal out to whatever machinery is placed in their hands.

We have now traced fairly completely I hope, but necessarily in a very condensed manner, the evolution of the modern telephone set—the sub-station plant of the telephone system. There is one other complete telephone of interest—the operator's set. (Fig. 13). In the earliest switchboards, the operators, as I have just said, were provided with hand sets, and thus had only one hand free to work with. Within a year or two the head-band receiver was devised, and the transmitter was mounted separately, at first on a column or bracket, and later suspended by cords from the top of the switchboard. This arrangement, though it gave the operator both hands free, obstructed her view of the switchboard and relatively restricted her movements, since the transmitter hung in one position.

The breastplate transmitter gives the operator complete freedom of movement, and also makes the face of the switchboard clear of all obstruction, while it has an incidental advantage in giving each operator her individual set. The shield and case of the transmitter are of aluminium and are extremely light; the head-band of the receiver is pierced to reduce the weight. Many a load of jewellery carried for mere ornament is considerably more of a burden than the operator's receiver and transmitter.

The survey of the evolution of the sub-station shows that it has been greatly improved both in electrical and mechanical efficiency. The standard telephone set is now capable of talking nearly 2,000 miles, which is a vast increase of range. What such distances mean may be realised when it is considered that telephone conversation is now daily held between cities which are two days' journey apart by the fastest trains. Moreover, the same instrument is used for talking across the street as for talking over the longest distances. This is a variation of load which I think occurs in no other form of electrical apparatus, and it illustrates strikingly the flexibility of the telephone instrument.

The use which the telephone gets is severe. Much more severe nowadays than it was in the beginning. It must be remembered that almost every telephone, although we habitually speak of a telephone as representing a subscriber, is really used daily by a number of different people. The telephone is in the hands of the public without being owned by the user, and therefore, in the main, it is less carefully treated than it might be. It is also used a great deal more frequently than it formerly was. Many telephones are used both for internal communication and for the outside service, and it is not unusual for an instrument to be used from 50 to 100 times a day the year through. Notwithstanding these trying circumstances, the mechanical design has been so improved and the construction so much solidified and simplified that the telephone instrument rarely gets out of order. Many instruments remain in service year in and year out without giving serious trouble.

There are many special uses of the telephone and many different types of instruments have been designed for particular uses, on board ship, in military operations—where the telephone now plays an invaluable part—in the conduct of railway and tramway services, and in mining, diving, and other work.

Specimens of some of these special types of telephones, lent by the General Electric Company and by the Western Electric Company, together with some highly interesting instruments from the priceless collection of historical apparatus at the Post Office, lent by Mr. J. Gavey, Engineer-in-Chief to the General Post Office, were exhibited on the lecture table.

THE INDUSTRIES OF MOROCCO.

The best known, if not the most important industry of Morocco is the manufacture of carpets. The Rabat varieties are the most esteemed, and these somewhat resemble Smyrna carpets, but vary considerably in size. They are remarkable for their very brilliant colouring, red predominating. The number of these carpets sold annually exceeds 4,000. The process of manufacture, according to the "Annuaire du Maroc," is a careful and a very long one, the work being exclusively confined to women, who have acquired remarkable proficiency in it. Notwithstanding the reputation these carpets enjoy, very few of them are exported from Morocco, the natives—by whom they are greatly appreciated—preferring to keep them for their own use in the country itself. Of those which are found in Europe, the majority are manufactured at Casablanca or at Mequinez, and they are of a distinctly inferior quality. At Mequinez, the manufacture of carpets, which at one time was a well-developed industry, has lost much of its original importance. Another industry which affords employment to a considerable number of people, particularly at Salé and Ouezzan, consists of the manufacture of a kind of woollen tissue known by the name of "Hombel." At Salé, eighty native

houses are engaged in its production; At Ouezzan, about forty; and a few at Tetuan. The leathers manufactured at Tafilet, as well as those of Marrakech, Fez, and Tetuan, are well known, and enjoy a good reputation. They are remarkable for their supple qualities, which they owe to a prolonged maceration in certain vegetable substances the nature of which does not appear to be generally known. Their red dye is obtained from the nuts of a tree called "Takaout" which chiefly grows on the borders of Oued-Draa. Attempts have recently been made to acclimatise this tree in Algeria, but with what results is at present unknown. Many of these leathers are also dyed yellow, and these are used in the manufacture of the slippers which are so much in vogue in the Mussulman world. These slippers, manufactured in Morocco, are greatly used by the natives, and are exported in considerable quantities to Egypt, Algeria, and the Sudan. At one time silk tissues and embroideries, which are still products of Fez, were manufactured with silk coming from Djebel. The raw material now comes from France and Italy. The celebrated pottery, earthenware and mosaic industries, so much vaunted in the middle ages, appear no longer to exist, only a few enamels being still produced in Fez and Saffi. The milling industry in Morocco is carried on in a very crude and primitive manner, even in the preparation of olive oil the crushing of the fruit is effected by two mill stones. There are, however, indications of an attempt to erect properly constructed mills, principally at Tangiers, where the Sultan, twenty-five years ago, built a steam mill, which has since been abandoned. This is an industry in which Europeans, principally Frenchmen, engage very largely, and at the present time there are five mills worked by steam at Tangiers, one at Laraiche, one at Saffi, and one at Mogador, owned by French firms. A native industry, of which Europeans appear to be taking possession, is the manufacture of soft soap, of which the inhabitants of Morocco use considerable quantities. These soaps are manufactured very easily without any particular knowledge, scientific or otherwise, being required, and the products of the country alone are used in their composition. At Tangiers, and at Mogador, this industry is in the hands of French firms. Two manufactories of farinaceous substances, one in Tangiers and the other at Mazagan, both French, almost suffice for the requirements of the coast ports. The Sultan has recently admitted their products to the benefits of the coasting trade. The manufacture of cigarettes has during the last few years greatly increased. Independently of the establishments which have for some considerable time past been in existence at Tangiers, a factory has recently been established at Casablanca, and its working has been attended with some success. Mineral waters are supplied by Tangiers, Tetuan, Casablanca, and Mogador, while a distillery is working very satisfactorily at Laraiche. The distillation of alcohol is carried on very extensively in Morocco, where it is the exception not to find a still in every Jewish shop. It is stated to be a subject for regret that a spinning wheel has not yet been established at Laraiche, as the probabilities are that it would be fully engaged with the wool which is exported, as well as that which is worked up at present by the natives by a costly and tiresome process. In the manufacture of matches, one establishment is engaged at Tangiers, and at Fez and Mequinez an attempt was made fifteen years ago to produce sugar, but was not successful. The production of bricks is another local industry, and this is carried on at Tangiers. Almost the whole of the industries of Morocco (94 per cent.) are in the hands of the French.

THE GREAT ZIMBABWE.

The Times correspondent reports a lecture on the Rhodesian ruins delivered by Mr. MacIvor before the British Association at Bulawayo, which tends to upset previous theories as to the origin of these remarkable structures, and to rob them of the immemorial antiquity claimed on their behalf by previous explorers such as Mr. Bent, and Mr. Hall, whose paper on the subject read last April, will be in the recollection of Members. The lecturer went to Rhodesia last April, under the auspices of the Rhodes trustees and the British Association, and made a detailed study of Zimbabwe and other ruins. After careful investigation he decided that none of the ruins in Southern Rhodesia is older than the fifteenth or sixteenth century, and that they are the handiwork of African natives of the negro or negroid race under the dynasty known by the collective name of Monomotapa.

The buildings are essentially of a native kind or type common to-day; nearly all retain some original wooden stakes embedded in the walls; there is no trace of inscriptions on any of the ruins; stone and iron implements were found together; neither the buildings nor the other articles found, show traces of early Oriental or European influence; finally, the discovery of pieces of blue and white Nankin china and other articles of mediæval manufacture in the lowest parts of the foundations proves that such commodities were the object of barter before the buildings were erected. In the case of Zimbabwe, he controverts the statements that the foundations show a series of layers of different periods; but he admits that in one layer of sand charred wood found some way below the previous excavations may indicate an earlier period, though this is unlikely. Mr. MacIver maintains that the ruins were originally fortified places, usually enclosing a kopje built in the form of a rough ellipse following mainly the contour of the surrounding country. The so-called slave pits, described as pit dwellings, were originally citadels of their strong places round which concentric circles of walls were built. Zimbabwe, as the residence of the Monomotapa, was more carefully and elaborately built

than the others, but its plan is essentially the same. The elliptical temple would therefore be a trial fortress. The soapstone birds discovered by Mr. Bent represent totems. A race still exists—Kaffir tribe—with an eagle totem.

On the publication of the summary of Mr. MacIvor, Dr. Keane sent a letter to *The Times*, controverting his arguments, and strongly maintaining the views of the original explorers as to the extreme antiquity of the ruins.

HAT-MAKING SCHOOL IN PANAMA.

A central school of hat-making, and for the cultivation and improvement of toquilla straw, has been established in the district of Arraijan. The school is provided for by Government funds, and will be under the authority of the Minister of Public Works. Fourteen scholarships have been established, two to be filled from each of the seven provinces of the Republic of Panama. Besides the holders of these scholarships, pupils who so desire will be received in the school as externs, to the number of thirty-six. Applicants for scholarship must be not less than 15 years of age, of good conduct and health, willing and desirous of learning hat-making, have good eyesight, be of cheerful disposition, and, if possible, have had some previous knowledge of making hats from toquilla straw. Each pupil will be expected, as a return for his instruction, to undertake to teach the same industry in whatever place may be designated by the Government. In case of refusal to do so, his father or guardian will be called upon to repay all the expenses incurred by his education. The school was opened—according to the United States representative at Panama—on June 15 last, and the governors of all the provinces have been notified to inform the public and receive applications for admission. The three officials of the school have been selected, and proceeded in May last to Ecuador, where most of the "Panama" hats are made, there to engage the services of workmen.

CORRESPONDENCE.

MEXICO.

I have just returned from Mexico, and have been interested in reading the articles which appeared in the *Journal* in May and July last. From personal observations I can confirm, with regret, what is stated with regard to British trade.

English goods are appreciated and English people liked, but for some reason which I cannot fathom our manufacturers, with few exceptions, seem to take no steps to increase their trade with Mexico, although I am confident that the present turnover might easily be increased by 25 per cent. or more.

On this side scarcely any endeavour is made to ascertain what goods are required, and if catalogues are sent out and enquiries result, there are no opportunities of seeing specimens of the goods in Mexico, so that in sending orders it is necessary to work from a catalogue description—mostly printed in English—and trust to the article when it arrives being the same as the catalogue would lead one to suppose.

I regret to find that our Government, instead of increasing facilities, are about to take a retrograde step, as it is proposed that instead of having a Consul in Mexico city there should only be a Vice-Consul, notwithstanding other nations are represented by Consuls-General. Considering that Mexico city has 400,000 inhabitants, is well equipped with all modern appliances, and, above all, is the great distributing centre for the Republic, I am at a loss to understand the proposed change. A petition for presentation to the Foreign Office has been drawn up and signed by British business men in Mexico, and it is to be hoped that additional pressure may be brought to bear here to prevent the proposition being carried into effect.

In the article which appeared in the *Journal* of July 28th I notice a comparison between the international shipping 1885–6 and 1902–3, but should like to point out that the figures given do not answer any useful purpose in consequence of certain changes in the compilation of these statistics during the last few years, and further, on comparing the figures for 1902–3 with those which appeared in the Government returns, I find that they only represent one section of the international trade, viz., "the direct," the figures for vessels calling at various Mexican ports not being included. Further, the figures quoted are compiled according to the flags carried by the various vessels, but do not in any way afford a clue as to the countries from which they came. I append a statement "A," showing how this materially affects the data, and "B," the tonnage omitted by not including vessels calling at various ports.

To the Fiscal statistics for the first six months of the year 1898-9 is appended a note with reference to navigation, stating that important modifications had been made in regard to this branch of statistics, and it would therefore appear that as the bases differ it is not practicable to compare 1885-6 with 1892-3. It may, however, be of some interest to show how the totals inwards for 1898-9 compare with 1902-3 "C," and I also append "D," a comparison by countries, showing the figures for England, France, Germany, and the United States.

Of course a considerable quantity of high-class material enters Mexico by rail, and as mere tonnage gives very little indication of value, statement "E" will better show the progress made by each of these countries.

HOME INDUSTRIES.

Apples for Vintage.—It was stated in the *Journal* of September 1st that the cost of the first year's operations on an acre of hops properly dealt with was estimated by authority at £44 13s. The cost of planting an acre of apple trees for vintage purposes is much less but still considerable. In his evidence before the Departmental Committee on Fruit Culture Mr. J. Riley, who is a leading fruit grower at Ledbury, Hereford, gave his own experience. Of course the cost varies with different counties. Mr. Riley referred to Hereford alone, which has a larger average of orchards than any other county in the kingdom—27,221 acres against 27,184 of Devonshire—taking the average of the years 1901-03. The cost of each tree, 2s.; digging out holes and planting, 2d.; cutting and putting on wire, 1d.; seven feet wire netting three feet wide, 6½d.; twelve yards of barbed wire, 5½d.; a wooden staple of a fair size, 2d. or an iron staple 9d. That makes a total cost of 4s. 2d. a tree. In Herefordshire 40 to 50 trees go to the acre, which would make the cost of planting about £10. In Kent as many as 300 have been planted to the acre. Of 27,221 acres of orchards in Hereford about 75 per cent. is vintage fruit, and the value of the fruit alone in an average year may be put at £200,000, the remaining 7,000 acres being pot fruit.

On the whole it would seem that cider fruit pays as well as apples grown for dessert or culinary purposes. It suits many people to grow cider fruit. They can make a success of it when they would not be successful with cooking fruit or dessert fruit. Many varieties of cider fruit are not so susceptible to insect pests. What are called the bitter-sweet apples have a very leathery skin, and they are not so likely to be attacked by the codlin moth, for instance. The blossom, too, is less sensitive. For these reasons the cider fruit tree can be relied upon to bear more regularly than some of the eating apples. The cider fruit is shaken down, and not being hand picked takes less labour. Nor has it to be marketed at the exact moment. Many of the vintage apples keep well for several months if they are put down and are perfectly sound.

The Age of Orchards.—Unfortunately, a great many of the existing orchards are very old. The West Country orchard began to be planted at the end of the seventeenth century, flourished through the whole of the eighteenth century, and up to 1830, when the trees began to go rapidly down. A French work, published as far back as 1681, speaks of England as the country in Europe where the best cider is made, the cider of Normandy coming next. The life of a standard apple tree has been likened somewhat loosely to that of a man. Up to ten years it does not bear very heavily, after that its production augments rapidly to thirty-five or forty years. From then up to fifty or sixty it is at its maximum state of fertility, after that it declines, and at the age of eighty it is generally unprofitable to keep longer. But many of the apple trees still bearing are of almost fabulous age. Within the last ten years there has been a revival of interest in orchards, and it may be hoped that re-planting will now go on more rapidly.

The Period of Growth.—The chief impediment in the way—apart from the question of compensation—is the length of time intervening between planting and profitable return. It is a great drawback to cocoa planting to have to wait seven years for full bearing of the trees, but there is nothing like profitable return from a vintage orchard for ten years. But afterwards it is a gold mine. There is nothing like it in home agriculture for great profit. And it has to be remembered that, although the orchard does not give any adequate return until after it has been planted ten years, the grazing of orchards is as valuable as a piece of land that does not bear apples. In some cases it is more valuable on account of the shelter. It is very valuable in the spring, when farmers rely on it for their grass for their lambs and ewes, so that the apple crop is obtained at no sacrifice of income on the part of the landlord except the outlay of capital necessary to plant the trees. But that, as has been shown, is heavy.

The Question of Compensation.—The provisions of the Market Gardeners' Compensation Act (since incorporated in the Agricultural Holdings Act of 1900) allow a tenant of a holding, which it is agreed in writing shall be let or treated as a market garden, to plant fruit and erect the necessary buildings without having first to obtain the consent of his landlord, and at the end of his tenancy he is entitled to compensation, which often amounts to a very large sum an acre, and this acts as a deterrent, landlords refusing to let land for the purpose of the cultivation of fruit fearing the heavy compensation they may have to pay at the end of the tenancy. The difficulty has hitherto been avoided in some of the important fruit-growing districts either by the granting of leases sufficiently long to permit of the tenant recouping himself for the cost of his plantation (*e.g.* in Kent), or by the landlord selling his land in small holdings (*e.g.* in the Wisbech district), or by the outgoing tenant making arrangements with the incoming tenant (*e.g.* in the Evesham district). In fact the planting of fruit has continued to increase since the passing of the Act, but it is believed that it would increase more rapidly if landlord and tenant were in nearer agreement as to equitable procedure. Under present circumstances few landlords are willing, or, perhaps, are able to find the capital necessary to plant the orchards, and often tenants are very neglectful in looking after it. They only interest themselves in them when the fruit-bearing stage is reached.

Owners as Cultivators.—The Committee on the Fruit Industry, discussing this question, expressed the opinion that it would be far more satisfactory if the fruit growers were the owners of their plantations and market gardens. The fruit grower expends large sums of money on his holding in improvements which are permanent, or at least likely to last for a considerable time, and if he is successful he adds immensely to its value. In this respect, it is urged, his position is very different from that of the ordinary agricultural tenant in whose case permanent improvements are usually made by the landlord. Many of the witnesses before the Committee spoke of the advantages of "small holdings," and the great development of the Wisbech district was largely attributed to the fact that the growers had been able, in most cases, to buy their holdings. The desirability of ownership applies in special degree to the cultivation of small fruit, but orchards, too, would be better it is thought, if cultivator and owner were one.

Cider a National Drink.—There are many difficulties in the way of cider becoming a really national drink, as it is in the North of France. The farmer can always make a limited quantity of first-class cider, but a large number of farmers have not the technical knowledge, and they make cider anyhow. The juice is simply pressed from the fruit, and the fermentations entirely uncontrolled. Sometimes they turn out a good article, but it is a matter of chance. Then often the right kind of fruit is not planted. Speaking as to this, Mr. John H. Wootton, who is instructor in cider making to the County Councils of Hereford, Worcester, Dorset, Gloucester, Monmouth, and Salop, told the Committee that the stock in general use, as supplied by the nurserymen, is almost worthless to produce orchards of standard trees. The only stock that should be used, said Mr. Wootton, for standard trees in orchards is the crab stock, which you cannot purchase from any nurseryman in England, or from very few. All the old orchards, planted a century ago, were worked upon crab stock only. Now the common practice is, according to Mr. Wootton, to sow the pip of the apple, and it is really an apple stock, the most unsuitable stock, in his opinion, that could be used for any purpose. It is not a question with the nurseryman whether the trees will last five years or a hundred years. It is his business to produce them at as early a date as possible, and to be able to sell the trees that look the most suitable for the purpose.

Brewers and Cider.—Then cider making is a very intricate business which demands much attention and the farmer has many occupaticns and distractions. In the making of cider a similar process seems to be going on as is to be seen in breweries. Fifty years ago a great many public houses brewed their own beer, now they seldom or never do. In the same way the farmer, who used to make cider for sale is giving it up and the manufacture is going into the hands of the professional. It has been the same with wine making in France. Professional cider making has proved beneficial to the fruit grower because it has enabled his produce to be used to greater advantage and probably in greater quantities. Brewers, however, are not willing apparently to push the sale of cider. Mr. John Watkins, a fruit grower from Herefordshire, told the Committee that the tied-house system is very detrimental to the sale of cider, and he gave an instance. He was supplying, when they were free to take cider, fifteen houses which belonged to a firm of brewers who had about 250 houses. They came to Mr. Watkins and said, "You must quote us the very lowest lines you can for the supply of all our houses and we will tie our houses to your order, or we shall have our cider from someone else." Mr. Watkins agreed and the brewers at once issued a circular saying they had arranged with such and such a firm to supply their first-class cider but their tenants must clearly understand that they were in no way to push the sale of cider. The tenants of the houses at once lost all interest in it. They got nothing out of it, and they did not push the cider. The consequence was the cider makers did less with the 150 houses than with the 15. In many cases brewers do not allow their houses to keep cider at all. Another difficulty which restricts the demand for cider is the large quantity of aerated water sold as champagne cider, or sparkling cider, which does not contain a particle of apple juice. What cider makers would like is a legal definition of "cider," the fermented juice of apples. It will not be easy to get it. Attempts made to get a definition of "beer" have not been successful.

The Acreage in Orchards.—Just as hop growing, and small fruit growing, are desirable cultivations from the point of view of labour, so in a lesser degree is orchard cultivation for the purpose of cider making. Moreover, as with hops, there would seem to be less to fear from foreign competition. It pays the ordinary agriculturist better to grow vintage than pot fruit, and the cultivation employs more labour than the ordinary agricultural or pastoral farming. The acreage under orchard is steadily if not very rapidly increasing, more especially in England. The acreage in orchards in England in 1875 was 150,600; in 1885, 192,344; in 1895, 212,963; in 1904, 233,286. Over the same period it has increased in Wales from 3,052 acres to 3,748, and in Scotland from 1874 to 2,449. Taking Great Britain as a whole, the increase has been from 148,221 acres to 239,483 acres. It can hardly be doubted that the increase would be much more rapid if only the compensation question were satisfactorily solved. Landlords would then be more willing to plant, or to allow tenants to do so. But there is also need of better knowledge on the part of farmers as to the proper treatment of orchards, and a better system of manufacture.

Journal of the Society of Arts.

No. 2,757. VOL. LIII.

FRIDAY, SEPTEMBER 22, 1905.

NOTICES.

"OWEN JONES" PRIZE.

This competition was instituted, in 1878, by the Council of the Society of Arts, as trustees of the sum of £400, presented to them by the Committee of the Owen Jones Memorial, being the balance of subscriptions to that fund, upon condition of their expending the interest thereof in prizes to "Students of the Schools of Art who, in annual competition, produce the best designs for Household Furniture, Carpets, Wall-papers and Hangings, Damask, Chintzes, &c., regulated by the principles laid down by Owen Jones." The prizes are awarded on the results of the annual competition of the Board of Education, South Kensington.

Six prizes were offered for competition in the present year, each prize consisting of a bound copy of Owen Jones's "Principles of Design," and a Bronze Medal.

The following is a list of the successful candidates :—

Arndt, Paul, Battersea Polytechnic School of Art, London, S.W.—Design for a Table-centre.

Elkins, Percival S., School of Art, Bath.—Design for Sgraffito Plaque.

Bickerstaffe, Arthur, School of Art, Macclesfield.—Design for Silk Hanging.

May, Margaret E., School of Art, Carlisle.—Design for Wall Tiles.

Hood, Wilfred M., School of Art, Nottingham.—Design for Wall-paper.

Stott, Sarah J., School of Art, Leeds.—Design for Cretonne.

The next award will be made in 1906, when six prizes will be offered for competition.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

TELEPHONY.

By Herbert Laws Webb.

Lecture II.—Delivered March 20th, 1905.

Telephone Lines.

The problem of the telephone line plant has to be studied under a variety of different aspects, and those aspects undergo change as conditions change. In the earliest days the problem was simply one of obtaining effective telephonic transmission over distances of a few miles. Even with the relatively crude line practice which telephony at first adopted from telegraphy, that was no difficult matter. But telephone wires in cities rapidly multiplied, and the distance over which telephonic transmission was demanded rapidly grew; under these conditions it became evident that telephony required totally different line design and construction from telegraphy. As the number of wires required in a given area increased, and the distance over which commercial talking was demanded stretched further and still further, telephone line practice diverged still more widely from that of the telegraph. The massing of wires in large cities made the use of cables and underground conduits a necessity; and this introduced two big problems of practical and commercial importance—the design of telephone cables for underground city lines which should still enable the subscriber to talk over the longest distances which the trunk-line or long-distance system might reach, and the effective and economical distribution of tens of thousands of individual wires from a central building to tens of thousands of individual buildings. This distribution problem alone—

the segregation of a waterspout of wires into a myriad of drops scattered over square miles —might well occupy an evening's discussion. Nor have the limits of the problem ceased to expand. With the growth of telephone development every large city telephone system has become linked to suburbs and other towns by circuits in great number; as the number of these circuits grows it becomes necessary to put them underground. Consequently, whereas ten or twelve years ago we thought we were doing great things in talking ten or twelve miles through underground cables, we now need to talk twenty or thirty miles, and we need cables which will not only talk these distances but will talk when joined on to an overhead line a thousand miles or more long. And all these things must be done at such cost that the results will be commercial.

In telephonic transmission we have three evils to guard against—attenuation, distortion, and induction, or interference. We are dealing with a relatively small current, and although the telephone receiver is so sensitive that it responds to immeasurably small currents, still, attenuation of the received current to an extreme degree means loss of loudness, and a certain fairly well understood standard of loudness is essential for commercial talking. Distortion is even more important than attenuation, since if certain of the waves are displaced or lost in transmission some of the characteristic sounds of speech disappear; there is loss of clearness, speech becomes difficult, and finally impossible. Attenuation is due mainly to resistance, to loss of energy expended on heating the conductor; it is also due to leakage and to capacity, to absorption of energy in charging the dielectric; distortion on the other hand is due to capacity, to the entire absorption or displacement of some of the waves. Induction, or interference by induced or foreign currents, was the great enemy of telephonic transmission in the early days of the industry, when the use of single wires was general. The sensitiveness of the telephone is so great that it responds to feeble currents which would not be noticed on any other commercial circuits. With single wires foreign currents often made telephone circuits wholly unworkable. Even the metallic circuit is not of itself a complete guard against foreign currents. To prevent interference it is necessary that the circuit be evenly balanced, that each side be of equal value in resistance, capacity, and insulation, and that each side of the circuit be equally exposed to sources of interference.

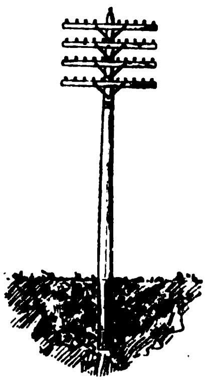
Professor Hughes, in 1879. first pointed out the necessity for an evenly-balanced metallic circuit for effective telephonic transmission, and he it was who devised the twist system of transposition by which the two wires of the circuit, revolving around each other, are equally exposed throughout their length to all external sources of disturbance. This transposition, which results in the induced currents which appear in the two wires neutralising each other and so causing no disturbance in the telephones, is carried out in all telephone metallic circuits. In open overhead wires it is done either by changing the relative position of the wires at every pole, as suggested by Professor Hughes, or by changing their position at certain definite intervals. In cables and insulated wiring of all sorts it is done by twisting the two insulated conductors of a pair together. This transposition or twisting is absolutely necessary to prevent cross-talk, or overhearing by inductive interference, when several circuits are carried on the same supports or in the same cable. With parallel circuits, overhearing or cross-talk from one circuit to another may be as distinct as if the lines were in metallic contact.

In the early days of telephony, in fact, for some considerable period, the balanced metallic circuit was looked upon as a counsel of perfection, at any rate, as far as purely local service was concerned. For some time it was a struggle between correct theories—or, to put it more accurately, correct practice—and commercial necessities. The business as a business was young; it was largely experimental, and there were many difficult problems on all sides; money was scarce, it went quickly and came back slowly. (It is curious that telephone service seems to be the one service which the public, with a remarkable unanimity, has always shown great unwillingness to pay for.) So the single iron wire of the telegraph was at first generally used for the telephone. Gradually various considerations caused the single iron wire to be substituted by the single bronze or copper wire. The low conductivity of iron, its high self-induction, and its great weight caused it to disappear from large telephone systems at a comparatively early date. Still, iron wire has its advantages; it is cheap and it is strong, and for local and short-distance service its low conductivity is no drawback. Where telephone service has to be done very

cheaply, iron wire is largely used to-day; for example, by the small co-operative telephone companies in Scandinavia, and by the rural and small independent telephone companies in America.

In all large systems, first phosphor or silicium bronze and then hard-drawn copper soon entirely superseded iron wire. The invention of hard-drawn copper wire gave a great impetus to the building of long distance telephone lines, as hard-drawn copper furnished a conductor of mechanical strength practically equal to that of iron, and of greatly superior conductivity. Without this useful invention, due to Mr. Thomas Doolittle, of Boston, long distance telephony might have languished many years. With it, the range of the telephone rapidly increased, and, in the eighties, an extensive business in long distance telephony sprang up.

FIG. 14.



AMERICAN TELEPHONE POLE LINE CONSTRUCTION.

The construction of telephone lines differs considerably from that of telegraph lines. Since the volume of business done is greater, and every line consists of two wires, the number of wires in a line or route is usually much greater, and this requires a more economical use of the pole than is customary with telegraph lines. Early telegraph practice placed only two wires on a cross-arm. In telephone lines eight or ten wires are placed on a cross-arm; the usual American practice is ten wires, English practice eight wires. The use of a large number of wires on a line involves the most substantial form of pole line construction; the standard American practice is to place 40 poles to the mile, giving a span of 130 feet, and to stay or brace every pole where any unequal strain occurs. In the early days of long distance telephony in America, it was customary to use very tall poles—poles of 60 and 80 feet were not uncommon—in the endeavour to carry the wires well above other lines and trees. These high poles were not a success, as the leverage of the heavy weight at the top brought them down in the severe snow-storms which are so frequent in an American winter. With wet snow, and any wind at all, the strain is irresistible; I have seen new poles, 14 and 16 inches in diameter at the butt, snapped off or pulled out of the ground by a very moderate fall of snow. As a result of these experiences the general use of very tall poles was abandoned, and the standard pole is now about 36 feet.

The use of heavy copper wire and the systematic transposition of the circuits again differentiate telephone line construction from that of telegraph lines. In order to obtain effective transmission over long lines it has been found necessary to use much more copper in telephone circuits than is used in overhead telegraph circuits. The longest lines in America are built with 435 lb. copper. In Europe, partly because undue value was given to theoretical considerations, partly because the transmitters used in Europe have generally been less powerful than those in use in America, much heavier wire has been used for long-distance lines. Some European lines are built of 600 lb. wire, and the "backbone" trunk from London to Glasgow is of 800 lb. copper. Thus, in talking from London to Glasgow one speaks over nearly 300 tons of copper, worth, for the metal alone, over £20,000. A New York to Chicago eircuit, nearly two and a half times the distance, contains less than 400 tons of copper.

The transposition of telephone circuits is a very special feature of their construction. Unless it is carried out with scrupulous care and accuracy the circuits become noisy and inefficient. In Europe the twist system is used more generally than the transposition or cross-over system. In America the transposition system is used exclusively; so that each method has its adherents. Each gives good results in producing silent lines. A circuit built on the twist system is beautifully silent, but it is very sensitive to any loss of balance. It has one practical advantage over the transposition system in that the method of construction is uniform throughout—each wire changes its position regularly at each pole. In the transposition system the various circuits are transposed at different intervals, the number and distribution of the transpositions

being determined by the length of the line and the number of circuits. This method gives a line of better appearance, since the wires change places only on the cross-arms and not between, and is better adapted to dealing with a large number of circuits; but since the scheme is more complicated it gives more opportunity for mistakes to occur in course of construction and repairs. In either case it is obvious that the building and maintenance of telephone lines require great care and method on the part of the engineering and working force.

Since the capital cost and the earning power of long telephone lines are on such a large scale, it is essential to maintain a continuous service and to avoid serious breakdowns. It is no small feat to maintain in continuous working order overhead lines many hundred miles long, passing through all varieties of country—even through different climates; but long telephone lines are usually so solidly and carefully built that they are the last to go in times of severe stress of weather. In the great American blizzard of 1888, the telephone line between New York and Boston was the only one that stood up. Telegraph business between the two cities had to be done by cable, *viâ* Ireland.

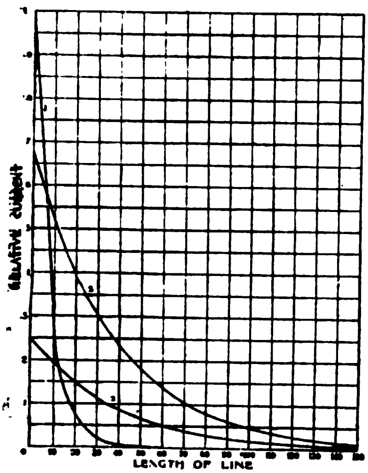
Quite recently a practical solution has been found for the problem which has always faced telephone engineers—the conquest of the attenuation and distortion due to capacity. It has always been recognised that the chief enemy to long-distance telephone transmission was the electro-static capacity of the conductor. In overhead lines, where the capacity is relatively small, the range of transmission has been increased by the use of heavier conductors, thus diminishing the attenuation; but there are commercial and practical limitations to this course, and eventually the effects of capacity assert themselves no matter what weight of copper be used. Mr. Heaviside long ago suggested that inductance might be availed of to counteract the effects of capacity in telephone circuits. Mr. Heaviside's mathematical and theoretical investigations have been of great value to telephone engineers, and this particular suggestion was destined to bear golden fruit in good time.

Professor Sylvanus Thompson, in a paper read before the International Electrical Congress of 1893, enlarged upon the possibilities of using inductances to counteract the effect of distributed capacity. Professor Thompson suggested inductances placed in shunt across the circuit. No experiments leading to any practical results were made, I believe, on these lines, and the original experiments made on the basis of Mr. Heaviside's suggestions were made with lumped inductance and were a failure. It remained for Professor Pupin to discover, by mathematical investigation and laboratory experiment, that the correct method of overcoming distributed capacity is to insert distributed inductances in series in the line. This was a brilliant discovery, one of incalculable value; a contribution to the art of telephony of which science, whether you call it raw or refined, may well be proud. The manner in which inductance coils for increasing telephonic transmission should be made, and their distribution on the line in accordance with its electrical properties, were worked out by Professor Pupin, and the beneficial effect of the use of the coils has been amply proved in practice by much work already done with them by the American Telephone and Telegraph Company.

The loaded telephone line is one of the most remarkable developments in telephony; that the transmission over a telephone line can be markedly improved by inserting inductance coils in series seems so contrary to all previous telephone practice as to be almost uncanny. The use of the terms "loaded" line and "loading" coil, comes from the analogy of the loaded string. A cord loaded with weights, spaced at regular intervals, responds more readily to waves of certain lengths than the same cord unloaded. That represents mechanically the loaded telephone line. Reaction and action must be equal and opposite; the action of the capacity in absorbing a charge is counterbalanced, as it were, by the discharge of the inductance. The absorption of waves becomes equal for all frequencies, and the circuit is rendered distortionless. In actual practice, the loading coils have already achieved most valuable results, although much detailed work has had to be done, as might naturally be expected, in applying an invention of this sort to practical conditions. Not only have the mechanical and electrical design of the coils required much study and experiment, but it has been found in practice that if ordinary telephone apparatus is joined directly to the end of a loaded line there is a large loss from reflection of the waves. To cure this evil, it has been necessary to apply tapered-off loading coils at the terminals; that is, a series of gradually diminishing inductances. Without the taper, the effect is, to use another mechanical analogy, somewhat

akin to that of a brakeless express train arriving full-speed at a station; the taper supplies an inclined plane which checks the speed. From a recent paper by Dr. Hammond V. Hayes, who has done a great deal of work in

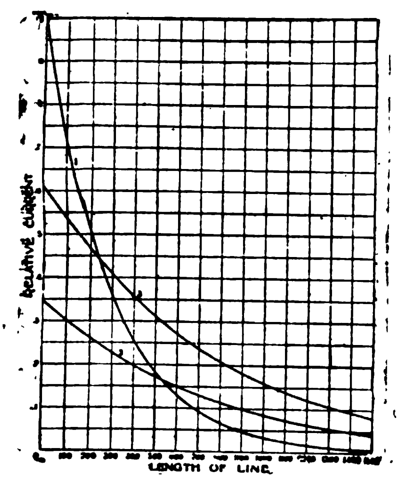
FIG. 15.



EFFECT OF "LOADING" ON CABLE CIRCUITS.

1. Unloaded line. 2 and 3. Loaded lines.

FIG. 16.



EFFECT OF LOADING ON OVERHEAD LINES.

1. Unloaded line. 2 and 3. Loaded lines.

he practical application of the Pupin method, extract two curves (Figs. 15 and 16) which show the results achieved in practice with oaded underground and aerial circuits. The irst curve relates to cable circuits having a oop resistance of 96 ohms per mile, and a loop apacity of ·068 mfd. per mile. Curve 1 shows the result on unloaded circuit, curve 2 loaded circuit without tapers, curve 3 loaded circuit with tapers. You will see that with the loaded circuit with taper terminals the talking is as good over 30 miles of loaded cable as it is over 10 miles of unloaded, and that the transmission at 80 miles with loaded cable is equivalent to that at about 19 miles of unloaded. It is difficult to exaggerate the importance of these results, because unloaded telephone cable to talk 20 or 30 miles, and to serve in connection with long distance working would be commercially prohibitive, both because of the cost of the cable and because of the space it would occupy. Yet cables of such length are becoming absolutely necessary in places where telephone development is high.

The second curve shows the effect of loading on an aerial line of 435 lb. copper. Here it will be seen that the improvement attained by loading is less than with cable circuits, although the curve shows that with loaded line the transmission is as good at 1,400 miles as it is at 700 miles on the unloaded line.

It is a feature of all the curves that the transmission on short lengths of line is poorer on the loaded circuit than on the unloaded, and that the initial current is lower; but the rate of attenuation per unit of distance is less on the loaded line, so that as the distance increases the loaded circuit rapidly becomes the more efficient of the two.

There are several reasons why loading is not so effective on aerial lines as on cable circuits. An important point is that the connection of the coils to open wires decreases the insulation. Also the larger self-induction of open circuits, in which the wires are much more separated than in cables, tends to counteract the effect of the coils. On cable circuits the use of loading coils, besides decreasing the attenuation, effects a marked improvement in the clearness of the received speech; this improvement in quality of speech is not so noticeable on aerial lines. I had an opportunity at New York last year of listening on a cable circuit of 60 miles of No. 16 wire arranged so that the loading coils could be switched in and out. Without the coils the talking was a confused indistinct mumble. When the coils were switched in the talking came up loud and distinct, with an effect that was positively startling. It was computed that the 60 miles of loaded circuit gave transmission as good as would be obtained on nine or ten miles of unloaded. But the real benefit and economy of the loading are appreciated

when it is considered that to get as good transmission over an unloaded cable for the same distance, 60 miles, the cable would hold but nine pairs of No. 4 wire. No telephone company could afford to use such a cable.

The actual coils used on loaded circuits are of copper wire on an iron core; the coil is made ring-shaped, and a coil for the aerial line referred to is ten inches in diameter and about four inches high. The copper resistance is 2·4 ohms, and the inductance ·25 henry. For cable circuits the coils are made of higher resistance, and therefore are much smaller. The exact design and the spacing of the coil depend on the character of the circuit to be loaded.

Telephone Cables.

The growth in the number of telephone wires in cities soon brought about the necessity of placing the wires underground. It then became necessary to design a special type of cable for telephone work. The underground wires in use for telegraph lines were unsuitable for telephone work, being too costly, too bulky, and of too high electrostatic capacity. Some of the very earliest underground telephone work was done with gutta-percha and indiarubber insulated cables. In Paris the telephone wires have always been underground, the elaborate sewer system of Paris providing a ready-made space for stowing away cables. In Paris gutta-percha cables were used for many years. In some of the earliest underground telephone work done in America rubber-covered wires were used. But it was soon seen that rubber and gutta-percha were electrically and commercially impossible for telephone work. It was necessary to have a cable which would give circuits of lower capacity, and would enable a large number of circuits to be put in a small space.

There had been various experiments with cables formed of cotton-covered wires placed in pipes kept filled with heavy oil, notably those of Mr. David Brooks. (One of the difficulties was to keep the oil in the pipe.) Development along these lines led to the production of cables in which the wires were covered with cotton and impregnated with an insulating compound, the whole cable being sealed in a lead pipe. The Patterson cable was the first in which the lead pipe or sheathing was formed continuously by a press on the cable. To a certain extent these impregnated telephone cables were a reversion in type, as the earliest underground telegraph cables were insulated with fibrous materials impregnated with compound and enclosed in a lead pipe. At first cables with straightaway wires were used, but in 1887 a specification for a true telephone cable, calling for wires twisted in pairs, was evolved.

These early telephone cables, dating from about 1887, contained 50 pairs of wires in a 2-inch pipe, and 50 or 52 pairs was for some time the capacity of a duct. Some of the early ducts were 2½ inch, but 3 inch has become the general standard size of ducts used for telephone conduits. The use of fibrous insulation at once brought down the electrostatic capacity of the conductor by 40 per cent. The electrostatic capacity of a rubber or gutta-percha insulated wire is about ·33 of a microfarad per mile; that of the first 50-pair Patterson cable was ·20 of a microfarad. It was realised that, as cotton or paper rapidly absorbs moisture, the insulation of the telephone cable really depended on the continuity of the lead sheath, and much concern was felt as to the effect of "pinholes" and cracks in the lead. Standard methods always die hard, and cables in which each wire was not separately insulated were at first looked on with much suspicion, especially by the makers of rubber and gutta-percha cables. Even telephone cable makers and engineers at first thought that the paraffin or compound filling was an absolutely necessary precaution against the too rapid spread of moisture in the cable, if the lead did go.

I daresay there are many men in the telephone business to-day who are uncertain as to the origin of the term "dry core," and who do not know that the core of a telephone cable was ever otherwise than "dry." As a matter of fact, the dry core came about because some of the filled cables in New York became extremely wet soon after they were put into the ducts. This was due to the proximity of steam supply pipes to the ducts. The heat liquefied the paraffin wax filling of the cables, with the result that the insulation went down and the capacity went up, with a complete disregard of specification figures. To cure this evil it was decided to try "dry core" cable, *i.e.*, cable of the same type without the filling of paraffin or resinous compound. This was considered an extremely risky experiment, as if a hole occurred in the lead sheath the cable would all be dead earthed in an hour or two. But it succeeded perfectly. It was found by experience that a filled cable lost its insulation by absorption of moisture almost as quickly as a dry cable. The fear of dry core disappeared, and it was experimented with extensively,

notably by Mr. Patterson. Paper was found to have a lower electrostatic capacity than cotton, and it was found that with dry core paper cable the capacity was only ·12 microfarad per mile. Consequently dry core very soon became the standard thing, and filled cables ceased to be made. Getting rid of the filling was a great boon to the cable makers, as it was the most troublesome part of the process of manufacture.

Taking advantage of the gain in space, and of the improvements in manufacture which experience suggested, cable containing 100 pairs was very shortly produced, using but a slightly larger diameter—2¼ in.—of lead sheathing, and the carrying capacity of the duct was at once doubled. A few years later, in the early nineties, the manufacture of telephone cables had so far progressed that 200-pair cable of 2½-inch diameter was a standard article. Dry paper had become the staple material for insulation. Much attention was paid to methods of wrapping the paper loosely on the conductors so as to obtain the maximum amount of air space and so a minimum capacity. In this way the electrostatic capacity of the conductor was brought down to ·08, ·07, and even to ·06 microfarad per mile. As more powerful transmitters were introduced, and as conduit space became more valuable, the extremely low capacity was abandoned in favour of a larger number of conductors in a 2½-inch pipe. This was obtained by giving the conductors greater compression and by using a finer wire.

Within ten years of the introduction of the telephone cable 400-pair cable had become a standard type, and the possible capacity of the 3-inch duct had been increased eightfold. To-day 600-pair cable is in regular use, and even 1,000-pair cable has been made for special purposes. The immense increase of carrying capacity which this steady increase in the number of conductors contained in telephone cables has given to the conduit systems may be imagined. It is not too much to say that the development of some large telephone systems would have been blocked long ago if telephone cables had not progressed beyond 50 or 100 pairs, as space could not have been found in the streets for the wires required. The cable makers may well be proud of the ingenuity and perseverance they have shown in making not merely two pairs of wires go where one went before, but eight and even twelve.

Turning now to the construction of cable plants, we have three main features—the conduits, the main cables, and the distributing system. Of the conduits much might be said; their name is legion, and the difficulties they present, especially in very large cities, are innumerable. The earliest telephone cables were laid without conduits, in wood troughs filled up with pitch or cement. The disadvantage of having telephone cables buried solid was quickly realised, and conduits became the rule. Very many different types of conduits have been devised for telephone work, ranging from iron pipe to paper. Creosoted wood ducts were an early favourite, and there has arisen a large family of the tile, earthenware, stoneware, and cement ducts. As a result of general experience, three main types of telephone conduit have survived—iron pipes laid in cement, earthenware ducts, and cement blocks. Each class of material has its advantages, but the conditions under which conduit systems have to be laid down vary so widely that it is difficult to give hard and fast rules. The supremely important point is that the ducts shall be well and truly laid. There are a great many ducts below ground in various parts of the world that through being out of alignment are not doing their full duty. A very small difference at the joints of a 3-inch duct makes it the equivalent of only a 2¾ or 2½, and seriously reduces its carrying capacity. Earthenware ducts, being made in short pieces, are more liable to this defect than other types. On the other hand, they are cheap and they are compact, and when thoroughly well built they become as solid as a Roman wall—even more so, because many old Roman walls were hollow. Iron pipes, being made in long pieces, are less liable to loss of alignment, and, being stronger, are more suitable where only a few ducts are required, or where the ducts have to be spread in layers; in other words they are more flexible. Cement blocks are largely used in Europe, practically not at all in America; they are not so flexible as iron pipes, they require a long length of trench to be opened at once in order that obstructions may be exposed, and they need extreme care at the joints. Broadly speaking it may be said that earthenware ducts have the advantage where many ducts are required in one run, and the obstructions do not impose frequent change in the formation of the conduit; iron pipes come in where obstructions are frequent, and where single ducts or single layers are required, and cement blocks come

in best where obstructions are few. In the Continental cities, where the streets are comparatively little encumbered with other pipe services, cement blocks are very popular, and they have also been largely used in English cities.

An important part of the conduit system is the manholes. A telephone cable unfortunately cannot be laid from point to point like a submarine cable. By reason of its size and weight it has to be handled in comparatively short lengths of a few hundred feet. To facilitate the drawing in and out, and the jointing of the cables, manholes have to be established at frequent intervals along the line of conduits, practically at every important street junction. These, in a large conduit system, become small underground chambers of brick, into which the ducts debouch. They require to be very solidly built, with a roof supported on girders, properly drained, and protected against the ingress of mud and water. The cover is usually made round so that by no possibility can it be dropped down on the cables. Of the drawing in and out of the cables, and the jointing, little need be said. It is arduous and laborious work, especially drawing out. The drawing in is generally done by a hand winch. In America modern practice is to use a motor-driven winch, which materially quickens the work. A wire is usually left in the ducts for hauling through the drawing-in rope, or the ducts are rodded with a set of rods similar to those used by our friend the chimney-sweep. Sometimes a light line is drawn through by a wooden tractor having a leather head which nearly fits the duct. This device is sent through the duct by air pressure, and is technically called a "mouse." The term has given rise to a newspaper story, which frequently appears, to the effect that telephone companies use a tame rat to take a hauling line through the ducts. I believe no rat has ever made himself so useful.

The jointing of gutta-percha cores, especially in submarine cables, is an operation of great solemnity. In the older telegraph text-books you will generally find it described largely in italics. Jointing a telephone cable is partly electrical work, partly plumbing. It is an operation needing much care and method, as several hundred pairs of wires have to be well jointed electrically, and all pairs must be jointed in their right order. In the early days there was not a little trouble from cross connections. The joints in the conductors are covered with little paper sleeves, and when all conductors are jointed the entire splice is dried out with melted paraffin or by heat. The break in the lead pipe is then completed by a short length of pipe, which is made one with the cable sheath by a plumbers' wiped joint at each end.

Some twelve years ago the telephone engineers in Paris, having a lot of defective cable on their hands and a central supply of compressed air available, bethought themselves of raising the insulation of the cables by pumping dry air into them. The process was a great success and has been largely adopted. A dry air pumping plant is now a recognised part of telephone equipment, and portable air pumps are used for testing joints and drying out bits of cable. An air nozzle is attached to every cable at the exchange and at the joint boxes. The air is dried by being passed over calcium chloride, and is forced into the cable at a pressure of about 20 lbs. to the square inch.

The difficulties of building telephone conduit systems in large cities are well illustrated by the character of the work done recently in central London by the Post Office. These views are typical of the difficulties encountered and of the special work which had to be done in order to overcome them. [At the lecture a large number of lantern slides illustrating conduit work in London was shown.]

In negotiating these obstructions many changes in the arrangement of the ducts had to be made. From the Central Exchange manhole ninety ducts start in one direction in three 30-duct conduits, each conduit consisting of six tiers of five ducts. Later on these combine into one conduit of nine tiers of ten each, and a bit further they spread into six tiers of 15 ducts. In one place 90 ducts have to be carried in two tiers of 45 each. There are many other instances where the conduits alternately concentrate and spread out in order to negotiate obstructions. In Queen Victoria-street, the arch of the subway had to be cut away and replaced by a steel roof to provide space to carry the conduits. Needless to say, so much interlacing of conduits with other pipe services and underground works entails much care in the engineering of the work and largely adds to the expense.

Telephone cables laid in well-built conduits are reasonably safe from risk of damage, but the whale which occasionally plays skipping-rope with a submarine cable, the sword-fish or shark which occasionally takes a bite through sheathing, jute and core, the fire built on the

beach which has been known to destroy a shore-end, all have their prototypes on land. A burst water main now and then floods manholes and finds out weak joints. A shark of a navvy now and then dives his pick through duct cable and all. It is a tribute to the solidity of telephone conduit construction that on one occasion a Post Office conduit in London was mistaken for a Roman wall and the persevering explorers drilled through a tier of ducts and cables before discovering that they had tapped twentieth-century civilisation. In New York a year ago a group of telephone cables were destroyed by fire. A large manhole had been taken out to facilitate work on the underground railway, the burlap wrapping put on to protect the cables from accidental blows caught fire, and some 5,000 wires were put temporarily out of service. In some parts of America a curious trouble arises from the freezing of water in the lateral pipes leading from the main conduits to the distributing points. The expansion of the ice crushes the cables and forces the conductors out of their paper wrappings into contact with each other and with the lead pipe. One large telephone company has organised a thawing brigade and equipment to deal with this trouble. The pipes are thawed out by the application of a heavy current, and it is found that when the ice is melted the cable returns to its normal condition. The waggon, equipped with petrol engine, dynamo and step-down transformer, is called in the expressive terminology of Western America, the "juice-waggon."

Distribution.

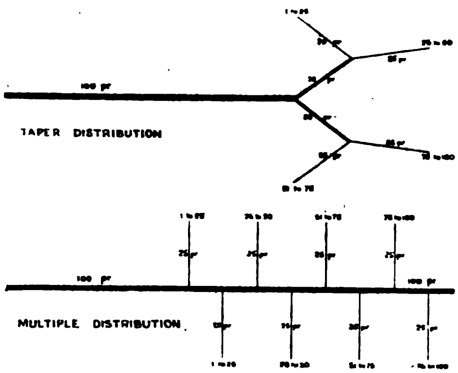
Both from an electrical and from a commercial point of view the most difficult part of a telephone cable plant is the distributing system. It is no light job to split up 5,000 to 10,000 pairs of wires, passing under the streets in large units of from 100 to 500 or 600 pairs, into individual pairs, each pair going neatly and economically to its individual instrument. You may have 10,000 pairs of wires at the exchange in 20 to 25 cables, compact and easily handled. At the outer terminals those cables have to be sub-divided into 10,000 individual pairs of conductors, each well insulated and electrically and mechanically perfect up to the terminals of the sub-station which it serves. The problem has only to be considered for a moment for its magnitude to be appreciated. Apart from the electrical and mechanical difficulties of dealing in this way with a great number of wires, there are considerations imposed by practical and commercial conditions which add considerably to the complexity of the problem. It is not merely a question of carrying a fixed number of wires to fixed points, so to remain permanently. The population of a telephone system is always changing. New users are constantly coming on and old ones are constantly going off. The new ones do not always come on where you expect them or where you want them, or in the proportion that you expect them. Often you provide, say, for 100 at point A and you get only 30, and at point B, where you provided for 25, 60 suddenly appear. Nor do new users always kindly appear at the exact points where old ones disappear. Often when a telephone user goes away the new occupant is one of those curious people who say they have "no use for the telephone." Again, many people seem to spend their lives in moving from place to place. That often means a line thrown spare at one point and another line wanted at the same time somewhere else. To sum up these and other considerations, what is required in a telephone distributing plant is flexibility, so that you can pick up new users wherever they appear and transfer the service of existing users from point to point as they require. This flexibility is only attainable by spare capacity, by having many more wires in the plant than there is actual use for at any given moment. This is one of the important difficulties and sources of expense in telephone work. But it has to be faced from the very beginning, or a state of blockade soon arises which is most disadvantageous. In all large city telephone systems, where development is provided for, you will find that taking the cable and conduit plant right through, not much more than 50 per per cent. is in use. Wherever there is only a small margin of spare capacity an accompanying feature is that many people have had applications for telephone service on file for long periods, that there is great public dissatisfaction, and that the business is carried on under artificial and unsatisfactory conditions.

In the early days of telephone cable work the spare capacity was carried right through the plant. The cables were split up and tapered down so as to carry a few pairs to each of a number of distributing points. Experience showed that this was building the cable plant upside down, that the flexibility was wanted above all in the distributing plant, and that the best economy and flexibility were attained by using large main cables and

by putting the spare capacity in the distributing cables. In this way main cables and conduits are used with relatively high efficiency, and, with several distributing wires for each pair of conductors in the main cables, any main cable pair may be extended to any one of several different points, which gives the necessary flexibility.

This is done, broadly speaking, in two different ways: by multiple distribution—that is, by tapping from the main cable the same pairs at two or more points—and by terminating at junction or distribution boxes a

Fig. 17.



Taper and Multiple Distribution.

larger number of distributing conductors than main conductors. The distributing cables are carried through the buildings to be served, and split up at distributing boxes into smaller cables as required.

Several different ways of direct underground distribution have been worked out in practice. In America many types of distributing ducts, with direct pipe connection to the houses to be served, have been tried. The principal objection to distributing ducts is their high cost. In New York a method has been worked out called the "block distribution" system; a main cable is carried into a block of buildings and connected to a junction box, and from this junction box radiate distributing cables, which are carried through the cellars and along back walls to small distribution boxes, from which single pair conductors can be taken as required. A somewhat similar system is used in Sweden and in the new work in Moscow and Warsaw. In the London Post Office system the distribution is done by means of pavement ducts and handholes or small joint boxes. To the main cables are connected, by means of special distributing boxes, groups of 7-pair distributing cables, and to these 7-pair cables are jointed single pair cables which go directly into the subscriber's premises through an iron pipe. This is very complete and substantial work; it costs a great deal, but the British taxpayer can afford to do things which a commercial concern would have to think twice over. And the great advantage of such work is that once done it is there as long as the street and the buildings are.

Fig. 18.

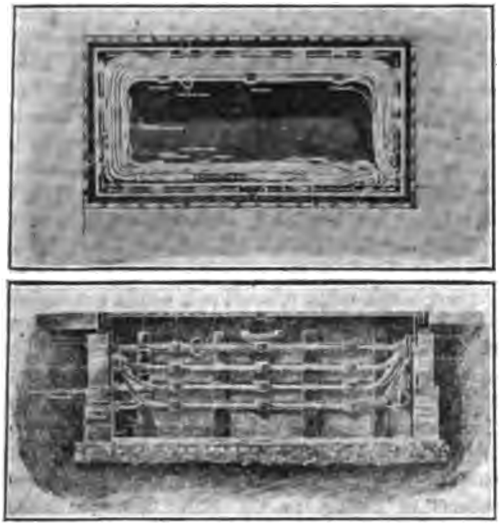
Distributing Box in Moscow. Main Cable 300-pair, Distributing Cable 60 10-pair.

In the Russian, or rather the Swedish system, the main cables, generally 300-pair, are taken to street distributing boxes, and from each box sixty 10-pair cables are taken to the neighbouring buildings, thus giving double the capacity in the distributing system that is contained in the main cables. The 10-pair cables are headed up to small wall distributing boxes from which 1-pair cables run to the instruments. Some distribution is done from roof fixtures and from iron distributing poles.

In small places where conduit work is too expensive, aerial cable distribution is now largely used. Pole lines built with cable are much less conspicuous than when built with open wires, and the cable lines maintain the

high and uniform standard of insulation required in common battery working. Cables are headed up and distribution done by ring or framework supports, sometimes with open wires, sometimes with 1-pair cables.

FIG. 19.



PAVEMENT DISTRIBUTING BOX.
(London P.O. System.)

FIG. 20.

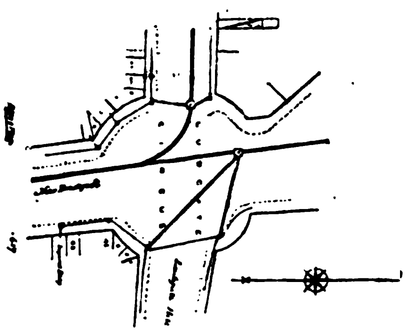


DIAGRAM SHOWING DISTRIBUTION FROM MAIN CONDUITS TO PAVEMENT DISTRIBUTING DUCTS, AND FROM DISTRIBUTING DUCTS TO SUBSCRIBERS' PREMISES. (London P.O. System.)

Summarising the evolution of the line plant of a city telephone system we see that it can be divided into four periods. In the first the line plant was entirely overhead and consisted principally of iron wire and single circuits with earth return. The second period was the transition from earth working to metallic circuit and from overhead to underground construction. During this period the plant consisted of copper wires, partly metallic circuit, partly earth circuit, and partly underground and partly overhead. In the third period we find the working exclusively metallic circuit and the main cables all underground, the distribution only being effected by means of overhead work. In the present period the standard of work in cities is a complete underground system with direct underground distribution. It is only in the outlying or suburban parts of a large city that modern practice countenances overhead distribution.

THE FRENCH CALCIUM CARBIDE INDUSTRY.

The principal centres of the calcium carbide industry in France are in the Alps and Pyrenees, particularly in the environs of Bellegarde, Grenoble, Nice, and Toulouse. At present there are eleven manufactories capable of producing 40,000 tons of calcium carbide annually. The demand is far from corresponding to the means of production, and the total output sold during 1904 may be estimated at 18,000 tons. The average yield of gas per unit of weight of carbide is about 40 gallons per pound. According to the American Consul at Marseilles, there appears to be no market properly speaking. The French manufacturers are completely protected against importations by the Bullier patent, and manufacturers of carbide and acetylene have arrived at an understanding whereby an average price has been established which enables both industries to exist. The manufacturers of carbide are said to lower their price every time they are able to do so without inconvenience to themselves. The merchandise is packed according to the wish of the buyer, in tins of 220, 143, and 110 pound capacity, or in case of shipment for exportation, in wooden cases lined with tin. Sales are controlled by the Société Commerciale du Carbure de Calcium, with headquarters in Paris. This company has a capital of £88,000, and has been chosen by the eleven producing concerns as their selling agent for the entire country. The cost price per ton of calcium carbide in Europe was estimated by Professor Lefevre, of the Ecole des Sciences, Nantes, in 1897, at from £8 to £10. There was nothing then, so he stated, to indicate the probability of these figures being sensibly modified. M. Pictet, however, in the same year, thought that the product might be made at the cost of a little over £3, by the use of a new furnace. Theoretically, said Professor Lefevre, one pound of calcium carbide ought to produce, by its action upon water, about seven ounces of acetylene. It has been stated by one of the most important of the French firms included in the Trust, speaking of the production of 1904, that this was disposed of at £8 per ton, the standard accepted and declared being about forty gallons of gas per pound. The product

at the factory realises £8 per ton, and the rate for the retail dealer is £14. These figures demonstrate the advances made in manufacturing since the publication of Professor Lefevre's treatise in 1897. Professor Lefevre concluded his study of the subject, as follows: "What is the future of acetylene? Is it destined, as certain of its defenders affirm, to supplant all other illuminants, and become the one source of light? It is difficult to foretell the future, but a complete triumph does not seem probable. Moreover the cost will certainly play an important *rôle*. The development of illumination by means of acetylene gas is subordinate to the selling price of calcium carbide. Acetylene has to fight against two powerful rivals. Coal gas, thanks to its numerous by-products, often permits of the establishment of prices so low as to defy competition. Electric illumination has also numerous advantages, even when more expensive, as, for example, intensity, security, preservation of the purity of the atmosphere, suppression of smoke, odour, &c. Acetylene gas, now, is distinguished by the simplicity of its preparation, and is therefore adapted to installations where the number of burners is too small to justify the erection of a gas plant or electrica station. It is specially adapted to hotels, villas, farms, isolated houses, ships, &c. For the same reason it may be employed in trams and railway carriages. There appears to be a long series of applications especially reserved to acetylene gas which assure it a special place in the list between its two principal competitors, gas and electricity."

TREES, HERBS, AND ROOTS IN WEST AFRICA.

Professor Abayomi Cole was instructed by the Governor of Sierra Leone to collect and report upon botanical specimens—herbs, roots, &c.—to be found in the forests of the West Coast of Africa, and his report has been received, and the following notes are obtained from it. The author points out that the economic and medicinal value of African forests are little known to the European world. Every year thousands of acres of forest lands, containing useful plants and trees, are destroyed, the loss of which is far greater than what may be gained in the single year's production of rice or corn, and the intelligent collection of which might have added greatly to agricultural profits, and made the forest lands more valuable. As an aid to the scientist who may not have seen the plants collected by Professor Cole growing in their native soil he has, in a few cases, furnished botanical or analytical notes along with his report.

The Khalmatamba is one of the most remarkable of West African forest trees. It is one of the African mystical medicine trees. The name, Khalmatamba, is of Susu origin. It is called "Orbai," the king (of trees), by the Timenes, and amongst many tribes sacrifices are offered to it. It is believed to have the power of curing every malady, and there is no important medicine (or greegree) of which it does not form a component part. It is known among the Mendes as Sowe-pue-ite, "Bondo matron's rod," as, on account of its sacredness and medicinal potency, the wand carried in procession by the leader of the Bondo (Women's Secret Society) Order is generally made from it. It has not been employed, to Professor Cole's knowledge, as medicine by any European doctor. The parts used by the natives are the bark and the leaves, and a fixed oil obtained from the seeds is a remedy used in cutaneous affections. This plant is employed as a "cure all," but specially it is the secret medicine of the Bondo doctors in the treatment of uterine disorders, and in many cases, the Professor says, it has been quite efficacious.

Professor Cole has collected beans from the Kundi tree (Nat. Ord. Meliaceæ, *Carapa guineensis*) and obtained oil from them. This oil is a specific in various kinds of skin diseases. It is very valuable in the progressive stages of small-pox, or as a preventive when combined with the powdered bark of the Fue tree. Its efficacy in some inland towns of the Protectorate, where no vaccination was performed during the recent small-pox epidemic, was, the Professor says, well marked. It is also anthelmintic, and an infusion of the bark is used for the cure of indolent ulcers. The Fue tree, referred to above, appears to belong to the Nat. Ord. Rutaceæ, *Xanthoxylon*. It is used by natives for cold, catarrh, hoarseness, and is a permanent and energetic stimulant. It is a specific for toothache.

The native tea (Efirin—tea bush, *Ocymum viride*), which belongs to the order of the Labiatæ, is described by Professor Cole as "diaphoretic, aromatic, with an astringent tendency following its primary laxative actions. It is also a diffusible stimulant. It is the African household remedy in colds and ordinary fevers, and is employed to allay the irritation of the gastro-intestinal mucous membrane. The active property is contained in a volatile oil, which could be seen through the leaves in dotted small glands if held up to the light. It is suspended in sleeping apartments to check the approaches of swarms of mosquitoes." The Professor says that the plant has undoubtedly properties which, whilst they may not avert the ingress of the mosquito altogether, decrease their numbers as soon as it is suspended in the apartment. The irritation and inflammation caused by the bite of the anopheles and other small flies are allayed in a short time if the distilled extract is applied over the parts. Professor Cole says that "this remedy will in due course be found a reliable prophylactic for malaria if not a cure for the disease." Tea is prepared from the fresh herbs.

Kimboyufe (Nat. Ord. Compositæ) is the specific for African yellow fever. It is employed in febrile diseases, and as a diuretic in dropsy connected with diseased kidneys. Professor Cole considers it a reliable remedy for "black-water fever." The powdered root is used as snuff in catarrhal affections, and taken internally it is also laxative and diuretic,

preventing waste and excretion. In the Professor's opinion "it demands careful investigation," and he has prepared and forwarded for examination 4 lbs. fluid extract of the fresh herbs.

One of the most important and valuable plants in West Africa is the Ojuologbo—Woody Vine (Nat. Ord. Rubiaceæ). It is used us medicine by nearly all West African tribes. It is the proper anti-malarial specific that has kept its reputatiou as such, on the Continent, for centuries, for it is noted down as a "valuable blood maker or purifier," and "fever expeller" in an ancient Sudan medical Arabic manuscript, written several centuries ago where the plant is mentioned as "Humidtaradu." It is a gentle stimulant to the cerebro-spinal centres, acting on the kidneys and urinary apparatus, inducing waste and excretion, improving digestive and nutrition, conditions indispensable to good health in tropical and malarious regions. Ira-igbo is a large forest tree used by natives to allay the spasmodic actions of tetanus, and as sedative in the excited conditions caused by insanity. It produces prolonged sleep, and is dangerous in physiological doses, when it may cause temporary paralysis or death. Rere belongs to the natural order Leguminosœ, Cassia Occidentalis, and its seeds, are used as coffee. They have beneficial effects on the kidneys and bladder. The leaves when ground and mixed with palm oil are applied on children as a remedy for convulsions. Virulent cases of ophthalmia, due to venereal taints, have been cured by the application of the juice of the fresh herbs to the eyes. The root is a specific for gonorrhœa, and is used for "black-water fever" and malarial dysentery.

TECHNICAL EDUCATION IN AUSTRALIA.*

The necessity for providing the means of imparting technical education has been unreservedly acknowledged in each of the States of the Australian Commonwealth, the annual combined expenditure in this direction being over £60,000, exclusive of the cost of land, buildings, &c. In Sydney, after successful experiments in the formation of classes by one of the State subsidised educational institutions in Sydney, a technical education board was established, which did good work until 1889, when the State Government assumed control of the movement, the work of technical education being handed over to the State Department of Public Instruction. The Technical College, forming the headquarters of the system, is one of the leading architectural features of Sydney. The fronts of the main structure are ornamented with Romanesque carvings in white stone, showing representative flora and fauna of Australia. The main entrance is formed by a triple arch, with two centre columns of polished bluestone or trachyte, flanked by two pilasters of the same material. The main building to which access is thus gained has three floors and a half-basement, and contains 28 rooms, many being well lighted, lofty, and suitable class-rooms. There is a chemical laboratory, and at the rear of the main structure are electrical engineering, plumbing, sanitary engineering, blacksmiths' shops, and well-equipped general engineering shops. In 1903 there were 477 technical classes in operation, of which 243 were held in Sydney and suburbs, and 234 in the country districts, while there were in addition 86 classes held in connection with the public schools. The number of individual students under instruction during the year was 13,232, and the average weekly attendance 8,671. In 1896 a technical college was opened at Newcastle, and a new college at Bathurst in June, 1898. In 1902 a technical school was built at Lithgow, and mechanical engineering shops provided at Newcastle. During the year the expenditure by the Government on technical education amounted to £26,459, exclusive of expenditure on the Technical Museum and branches. Fees to the amount of £8,707 were received from the students. In Victoria much has been done in promoting the work of technical education, a patriotic Victorian having assisted the earlier stages of the movement by giving £15,500 towards the establishment of a working men's college. In 1903, there were eighteen schools of mines and technical schools receiving aid from the State. The total State expenditure during the year was £16,430, and the fees received from students amounted to £11,741. The average number of students enrolled was 3,173. In addition, classes in manual training and in cookery and domestic economy are held at various centres, the net expenditure on these branches amounting in 1902-3 to £3,437. In South Australia the Adelaide School of Design in 1903 had 577 students. There were also branch schools at Port Adelaide and Gawler. The School of Mines and Industries, founded in 1889, received State aid in 1903 to the extent of £3,658, while the receipts from fees and sale of materials to students amounted to £3,691. Queensland is beginning to display increased interest in the movement, a board of technical instruction having been appointed in 1902, holding its first examination at the close of 1903, when 960 students were examined, two-thirds obtaining certificates of competency. In the same year there were twenty technical schools distributed through the State, with an enrolment of 2,600 students. The amount of fees, &c., collected was £13,385, and that of the expenditure £14,280, showing the system to be almost self-supporting. In Western Australia a technical school has been opened at Perth, having now an average attendance of 190, the annual expenditure amounting to nearly £6,000. Tasmania has also technical schools in Hobart and Launceston, the average attendance, including that of the two Schools of Mines, being 540, the annual expenditure being under £3,000.

* Communicated by Mr. John Plummer, of Sydney.

HOME INDUSTRIES.

Honiton Lace.—There has been an interesting correspondence in *The Times* respecting the decay of the Honiton lace industry. The fact is indisputable, and the causes various. The Education Acts have had something, perhaps a good deal to do with it. Young girls have to be punctual at the schools, and parents are fined if they are kept at home. Then fashion plays its part. Of late, Irish laces and embroideries have been in favour. And price is always one of the factors that account for a decaying industry. Not only is the market flooded with the cheaper kinds of Belgian, which an uninstructed public buy as "Brussels," but the remuneration of the lace workers at Honiton has been miserable. There are no direct dealings between the Honiton worker and the buyer of her lace. The worker sells to the dealer, the dealer to "the trade," the trade to the public. The public pay a high price for Honiton lace, but the women who make the lace can only earn a pittance at it, although Honiton lace-making is a difficult and delicate art. It has been said that the secrets of the trade are no longer taught, and that the County Council of Devon are neglectful of their duty in this respect. These statements are not supported by evidence. On the contrary, Mr. Kennet-Weir, who is chairman of the Lace Sub-Committee of the County Council of Devon —a position that is in itself an answer to the charge— says that the Council have "entrusted an annual sum of money to a sub-committee composed of county councillors and ladies interested in the art, who have engaged a competent instructress, and have established classes in various centres by whom a great deal of excellent work has been done. The classes are generally well attended, and many requests for the establishment of others have been received." Nor is it correct to say that the younger workers have no longer a knowledge of those intricate and difficult stitches employed in the manufacture of Honiton lace.

Better Organisation Wanted.—It must always be a matter for regret when a home industry, which can be pursued without serious outlay for plant, and which enables the worker to add to a scanty income by labour that does not take her from home, or interfere with her ordinary duties, decays and dies. But the remuneration must have some relation to the work, and this it has not at Honiton. Cannot the middle man be eliminated? Mrs. Ada Slack, the joint honorary secretary of the Diss Association of Workers in Honiton Lace, says that four years ago a small number of ladies belonging to Diss "conceived the project of introducing into their own neighbourhood an industry that should enable women to earn money within their own houses without the need of leaving their domestic duties," and they decided that lace-making best met the want. Thereupon they formed themselves into a committee and began the making of Honiton lace, which has been so successful that at the Home Arts Exhibition last May sixteen Stars of Merit were awarded to their Association. But the lace made at Diss escapes the middle man, and so the worker is able to secure a wage worth working for. Cannot the ladies of Honiton form a similar Association? It at Diss, why not at Honiton?

The Bee Exhibition.—The Bee Exhibition at the Crystal Palace which closed on Saturday serves a useful purpose in reminding the many thousands who visited it of the possibilities of bee culture. With the growth of the acreage under fruit bees are more than ever necessary. One of the drawbacks to fruit-growing is the unfruitfulness of trees. It is due to many causes, and not least to insufficient bees to fertilise the blossoms. Rain very often occurs during the blossoming season and washes the pollen away from the blossoms, and insects, particularly bees, are necessary to fertilise. They are necessary, too, for the cross-fertilisation of the blossoms. Certain fruit trees are self-sterile, that is to say, they require pollen from other trees to fertilise the blossoms. And this self sterility is more noticeable when fruit trees are planted in large blocks, with one variety of apple. In California they have found it necessary to plant other trees, which they call pollenisers, to provide the pollen for fertilisation. They generally plant these trees in rows among the other trees, and they have, of course, to select trees that flower about the same time, so that the insects can carry the pollen from one tree to another and so fertilise the blossoms. For example, two apples are grown very extensively in California, the Bellefleur and the winter Pearmain, both very fine apples. The time of flowering is twenty-six days for the Bellefleur from the time the first blossoms open until the last blossoms drop. In the case of the Pearmain the period is twenty-four days. These apples planted by themselves are very shy bearers; probably only one bud in ten would set. Therefore they plant other trees as pollenisers. The one used very extensively is the Astrachan, because it blossoms with the Bellefleur for twenty-two days, and blooms eighteen days at the same time that the Pearmain blooms.

The Bee as Fertiliser.—The bee is more useful and effective for carrying pollen from one variety to another than other insects, because in the spring, when fruit blossoms have to be fertilised, there are more bees flying than any other insect. It is reckoned that there are twenty bees to one of other insects. These might perform the same office, but they are not on the wing at that particular period. Nor is it only apples that are fertilised by the bee. They serve the same purpose with other trees, pears, cherries, plums, especially pears. And with small fruit too, strawberries produce much more abundantly if they are fertilised by bees. The bee has to work round the strawberry blossom. There are no less than 200 fertilisations of a large strawberry to

get a perfect fruit, and a strawberry hard and green on one side shows imperfect fertilisation. It follows that all fruit growers should keep bees. Mr. T. W. Cowan, who represented the British Bee Keepers' Association, told the Departmental Committee on Fruit Culture, in his very interesting evidence, that there ought to be at least one hive per acre of fruit. Of course wild bees are as useful as the others for fertilising the blossoms, but with cultivation wild bees become exterminated. When orchards are properly cultivated there are no wild bees found in them. The ground is ploughed up and the bees are not able to make their nests in the ground, so that the number of wild bees is reduced, and their are fewer insects for fertilisation.

Bees at Toddington and Histon.—The fruit-growers as a body are not sufficiently alive to the necessity of bees for the purposes of fertilisation but some have recognised their value, strikingly proved at Toddington, in Gloustershire, where a large acreage was put down to fruit some twenty years ago by Lord Sudeley. The orchards on the property were suffering from unfruitfulness. The trees were almost a failure at one time, until Lord Sudeley introduced bees, when the trees soon began to bear freely. Another illustration of the usefulness of bees in fruit grounds may be taken from the experience of Mr. John Chivers, at Histon, near Cambridge. He is the well-known jam manufacturer, and began keeping bees with the object of benefiting his fruit, and he has found them directly profitable apart from their service to his trees. In 1903 he got about 4,000 lbs. of honey, and made £100; last year he got 9,000 lbs.: probably this year the product will show still further increase; so that the bees not only serve a useful, and, indeed, necessary purpose in fertilising the fruit, they pay handsomely in honey for the trouble and cost of keeping them.

Bees a Profitable Home Industry.—Bees provide a very profitable home industry. A case is within the knowledge of the present writer of an agricultural labourer who has been able to buy a freehold cottage out of the profits of bee-keeping. It may be interesting to note how it works out. Take the most primitive kind of hive, the common straw hive or skep, which will long be used by villagers from its easy make and small cost. The cost of the skep may be put at 2s., and 1[redacted]warm to put into it. Other charges do not excee[redacted]king 14s. in all. The cost of feeding is small. Altogether the outlay for the year is probably covered by £1. In a good season one skep would produce 20 lbs. of honey, which the villagers would sell retail at 8d. per lb., say 15s. Next year the one skep has become three, and the revenue has increased from 15s. to £2 5s., which is mostly profit. It will be seen that in four or five years, with ordinary good fortune and natural increase, the villager would be putting aside several pounds per annum as profit. He can always get a sale for his honey. The man referred to above made his own market by working up a connection in his immediate neighbourhood, but even if competition has to be reckoned with, the village grocer is always ready to buy, and the wholesale price never falls below 6d. per lb.

If bar frame hives are used, the production and consequent profit are greatly increased. The produce from the hives is often from 40 to 60 lbs. Mr. Chivers's average last year was 50 lbs., and from one hive 150 lbs. was taken. Put the average at 50 lbs., and the wholesale price at 6d., that means 25s. from each hive, of which at least £1 would be profit. Bees can be kept in almost any part of the country, but they do best where they can get at sainfoin or white clover. It is astonishing that villagers do not more generally add to slender wages by keeping bees. The original outlay, as has been shown, is trifling, and looking after the bees is a pleasant occupation, making but slight call upon exertion, and the profits are large. Bees are subject to few diseases, "foul brood" being the most common and fatal, and it is highly contagious, but it is seldom found where the bees are properly cared for, and kept dry and clean.

The Letchworth Exhibition.—On Saturday last the awards were announced and prizes distributed in connection with the exhibition of cheap cottages erected at Letchworth. It has been a useful exhibition, directing attention to the very important question of rural housing, and although many of the model cottages put up are not suitable for an agricultural labourer's wants, others meet them. It cannot, however, be said that the exhibition has demonstrated that these particular cottages can be erected in the ordinary way for £150. Builder's profit, architect's fee, cost of carriage of materials, have been excluded, and it is idle to speak of actual cost without reckoning these. Moreover, vexatious bye-laws have to be taken into account. As was mentioned recently in the *Journal*, in 1863 the Society of Arts offered special prizes for designs for cottages for the labouring classes, the prizes to be "for the most approved designs for cottages with three bedrooms in each, to be built singly or in pairs, at a cost not exceeding £100 each." And it may be mentioned that Mr. Frederick King, a well-known fruit-grower of St. Ives, Huntingdon, told the Departmental Committee on Fruit Culture that he builds cottages for his labourers at a cost of £100 only, these cottages having three bedrooms and two lower rooms. It seems regrettable that wood is not more commonly used. It is found to answer well in the severer climate of the United States, and it is much cheaper than the materials now generally used in England. No doubt rural by-laws stand in the way, but there is ground for hope that before long the local authorities will be induced, in one way or another, to relax present restrictions upon rural cottage building.

OBITUARY.

Sir Wyndham Portal, Bart.—Sir Wyndham Spencer Portal, late chairman of the London and South-Western Railway Company, died on the 14th inst. at Malshanger, his Hampshire seat. He was born on July 22, 1822, and was educated at Harrow and the Royal Military College, Sandhurst. He was the son of Mr. John Portal, of Laverstoke, and succeeded his father in 1848 as proprietor of the Bank Note paper mills at that place. He was a cornet of the North Hants Yeomanry Cavalry in 1842, and captain 1853-65. In 1861 he was elected a director of the London and South-Western Railway Company. He became deputy-chairman in 1875, and succeeded to the chairmanship in 1892. The latter office he resigned in 1899 on account of increasing age, but he retained a seat on the Board until 1902. He was created a baronet in 1901 for his public services, and in recognition of his life-long labours for the improvement of the condition of the people. Sir Wyndham was elected a member of the Society of Arts so long ago as 1850, he held the office of vice-president in 1891-92, and as a member of the Council became a member of the Royal Commission for the English Section of the Chicago Exhibition of 1893. He had previously been Juror for several of the great exhibitions (Paris 1855, 1867, London 1862, Vienna 1873, and London Inventions 1885). From the Commissioners of the Exhibition of 1851 he received a medal "for services rendered."

GENERAL NOTES.

School of Art Wood-carving.—The School of Art Wood-carving, South Kensington, which now occupies rooms on the top floor of the new building of the Royal School of Art Needlework, in Exhibition-road, has been re-opened after the usual summer vacation. Some of the free studentships maintained by means of funds granted to the school by the London County Council are vacant. The day classes of the school are held from 10 to 1 and 2 to 5 on five days of the week, and from 10 to 1 on Saturdays. The evening class meets on three evenings a week and on Saturday afternoons. Forms of application for the free studentships, and any further particulars relating to the school may be obtained from the manager.

Turquoises.—In his report on the trade of Khorassan for 1904-5, Major Sykes, His Majesty's Consul-General, and Agent of the Government of India in Khorassan (No. 3499, Annual Series), refers to the famous turquoise mines at Nishapur. The mining is utterly primitive and unscientific, and owing to that, and to the fact that every Russian desires to possess a turquoise, good stones, Major Sykes says, are dearer than at a London jeweller's, but inferior qualities and matrix rule lower. There is a considerable export of large, light stones of a milky hue, or containing white veins, to India. These sell at most at 6s. per stone, and are generally speaking much cheaper, being valued in some cases as low as 1s. Stones known in Europe as matrix, which are termed arabi at Meshed, are exported in considerable quantities to that country. Prices rule slightly higher than the Indian stones owing to the demand from Europe which has sprung up during the last two years.

The Naples Aquarium.—The work on the new wing which is being added to the Stazione Zoologica is now, says Mr. Consul-General Neville-Rolfe, in his report on the trade of South Italy (No. 3496, Annual Series), making rapid progress. When completed the capabilities of the institution for scientific investigation in connection with fishing and other questions will be more than doubled, and the extension would seem to be much wanted, for during the spring months of the present year no less than 70 naturalists of all nationalities were engaged in various researches, and 15 applicants had to be refused admission on the account of the lack of accommodation. The completion of the new building, the ground plan of which measures 110 by 77 feet, will permit the following improvements to be made:—(1) The unique library of books on marine biology will be brought together upon the same floor instead of being distributed in various rooms; (2) laboratories and workrooms equipped under the superintendence of Dr. Henze for research in the physiological chemistry of marine animals will be the best and largest of their kind. They will occupy the second floor of the new building; (3) laboratories and workrooms for other physiological work in connection with marine animals will occupy the first floor; (4) a new photographic and artists' room will be gained; (5) a bacteriological laboratory; (6) some thirty new rooms for private study. The basement will be occupied by enormous aquaria and tanks, with the necessary engines for working the circulating pumps and for supplying power to the engineer's shop.

The Condition of Crete.—Mr. Vice-Consul Lascelles, reporting from Canea under date August 18, 1905 (No. 3494, Annual Series), gives a deplorable account of the condition of Crete. From want of means the inhabitants are unable to buy the necessary implements to cultivate their land. The condition of the port is going from bad to worse. It is filling with sand, and is already so barred that only small sailing boats can enter; steamers and large sailing ships have to anchor in the roadstead, and during the winter months they are often obliged to leave it owing to the prevalent north winds, and discharge their cargo at Suda. Improvement in the means of communication is a vital question for the island, but the only work worthy of mention is the construction of the bridge of Petiè, and a few small roads in the neighbourhood of the town.

Journal of the Society of Arts.

No. 2,758. VOL. LIII.

FRIDAY, SEPTEMBER 29, 1905.

NOTICES.

EXAMINATIONS.

The Programme for 1906 is now ready. The price of the Programme (containing the previous year's papers and the examiners' reports on the work done) is 3d. Copies can be had at this price on application to the Secretary, Society of Arts, Adelphi, W.C.

The Examinations are now arranged under the following stages:—Stage I.—Elementary; Stage II.—Intermediate; Stage III.—Advanced.

The subjects include: — Book-keeping, Accounting and Banking, Shorthand, Typewriting, Economics, Précis-writing, Commercial Law, Commercial History and Geography, Arithmetic, Handwriting, and Modern Languages.

The Examinations will commence on Monday, April 2, 1906.

The last day for receiving entries is February 28th.

The special subject for Commercial History and Geography is:—Eastern Asia, including the whole of the Chinese Empire.

The only alteration of importance in the Examinations for the present year is in Shorthand. Formerly all the different Stages of Shorthand were taken on the same evening. The different Stages will now be taken on two evenings: Advanced (First-class 150, Second-class 120 words per minute), and Elementary (50 words) on one evening; Intermediate (First class 100, Second-class 80 words per minute) on another.

Swedish has been added to the list of subjects in Stages II. and III., and the examination in Danish will in future be in Danish and Norwegian.

Examinations are also held in the Practice of Music, and Vivâ Voce Examinations in French, German, Spanish, Portuguese, and Italian. For information as to these examinations reference should be made to the Programme.

CANTOR LECTURES.

Mr. Henry Willock Ravenshaw's Cantor Lectures on the "Uses of Electricity in Mines" have been reprinted from the *Journal*, and the pamphlet (price one shilling) can be obtained on application to the Secretary, Society of Arts, John-street, Adelphi, London, W.C.

A full list of the Cantor Lectures, which have been published separately and are still on sale, can be obtained on application to the Secretary.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

TELEPHONY.

By Herbert Laws Webb.

Lecture III.—Delivered March 27th, 1905.

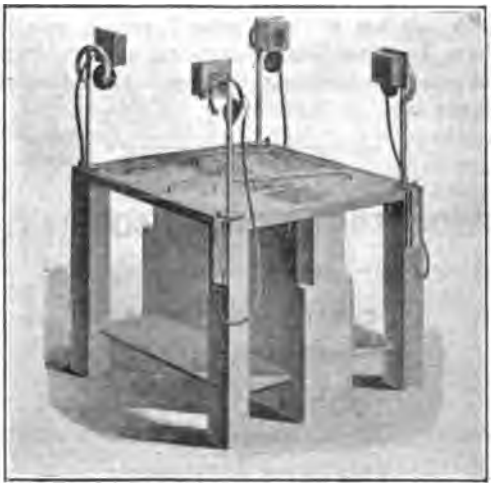
Telephone Exchanges.

Shortly after the telephone was invented and was proved to be a practical method of communication. the idea was conceived of combining the individual lines on which telephones were first used into exchanges, so that any line of a group could be connected to any other. The existing appliances for the purpose of combining lines together were telegraph switchboards, and the earliest telephone switchboards were simply adaptations of the appliances used in telegraph offices for interconnecting different lines with different instruments. The simplest form of telegraph switchboard was an assembly of brass strips, series of strips being placed at right angles to each other in such a way that any two strips could be connected by a pin. It was soon found that the functions of a telephone switchboard were much more complex than those of a telegraph switchboard. In the latter the requirement was to connect a certain

line to a certain instrument for a long period of time, and telegraph switchboards were usually not employed for the purpose of connecting one line to another.

In the telephone switchboard it was required to join any two of the lines at any time for very short periods, and the further requirement existed of receiving signals to indicate the desire for communication and to indicate the end of a conversation. It was further necessary that the attendant in charge of the switchboard should be able to send signals to the instruments at the distant ends of the lines in order to call the attention of the persons using the telephones.

FIG. 21.



EARLY LAW SWITCHBOARD.

The earliest form of signal used was an electro-magnetic indicator of a similar form to that used for electric bell purposes, and the earliest form of signal at the telephone instrument was the ordinary trembling bell. In the earliest days of telephone switchboard working, signals and bells worked by primary batteries were a great source of trouble, and one of the earliest special methods of working telephone exchanges was devised with the object of avoiding the use of signals altogether. This was the system called the "Law" system, so called because it was first put in use by the Law Telegraph Company, of New York. In this system a separate wire was used for transmitting the orders from the subscriber's telephone to the operator at the exchange, the subscriber speaking directly to the operator (who listened permanently on the order line) whenever he wanted to be either connected or disconnected. The complicated organisation of a telephone exchange system has been aptly compared to that of the human body, and in the Law system we get a very good illustration of this analogy. The special call-wire or order wire corresponds to the sensory nerve, and the individual wire of the subscriber's line to the motor nerve. A message is first transmitted along the sensory nerve, so to speak, and the result is afterwards obtained by manipulation of the motor nerve. The use of the Law system, involving two separate wires to each subscriber's station, one wire being common to a number of stations, was continued for a few years, but the radical disadvantages of the system, arising from the use of a large amount of extra line plant and from the numerous special methods of working required, prevented its general adoption and eventually caused it to disappear entirely from practical telephone work.

The majority of telephone engineers have worked on the lines of obtaining definite signals to indicate to the operator the progress of each step in the connection. The first type of signal, as has already been said, was the ordinary electro-magnetic indicator. This was operated at first by means of a primary battery placed at the subscriber's station, and later by means of a magneto generator, which would also serve in case of necessity for ringing the bell of the distant subscriber.

There was very rapidly developed a special type of telephone switchboard which departed entirely from the form of apparatus used for telegraph switching. The pin and strip were displaced by the flexible cord terminating in a metallic plug and the "spring jack" or socket switch, to the springs of which the telephone line was connected. By the insertion of the plug in the socket of the spring jack the metallic parts of the plug made contact with the contact springs of the spring jack, thus establishing a temporary connection between the telephone line connected to the springs and the metallic conductors in the cord attached to the plug. At the same time advantage was taken of the separation of the springs of the spring jack to disconnect temporarily the indicator from the line.

At first it was a difficult matter to handle large numbers of telephone lines in a single exchange. The apparatus took up consider-

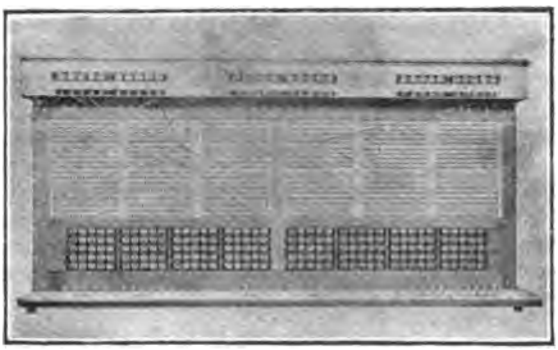
able space, and it was impracticable to bring the terminals of the various lines sufficiently close together that a connection between any two of them could be effected in a single operation. It therefore became necessary to employ more than one switchboard and more than one operator on each connection. A subscriber's call would be answered at one switchboard, and the call would be transferred to a second operator at a second switchboard where the line of the subscriber wanted was terminated. It was not uncommon in the early days of telephone exchange working to employ even a third operator, to nurse the connection, so to speak. It was difficult in those days to get people to talk together by telephone, and frequently they needed some encouragement from an operator at the exchange to induce them to engage in conversation.

The principle of the multiple switchboard, which is the fundamental principle of all large telephone switchboards to-day, was evolved as early as 1879, or within a year or so after the first practical telephone exchange was established; but multiple switchboards did not come into general use until several years later. The principle of the multiple switchboard is to repeat a spring jack or connecting point for every line before each operator in the exchange. An operator attends permanently to a certain number of lines, but, having before her a connecting point for every line served by the switchboard, she can

FIG. 22.

EARLY NEW YORK EXCHANGE.

FIG. 23.

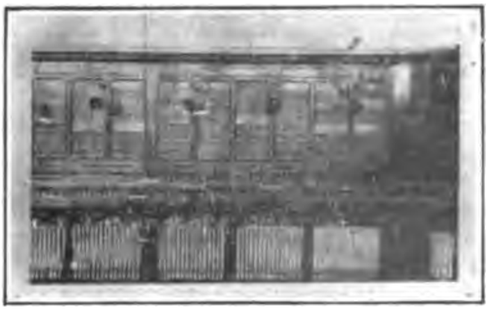


EARLY FORMS OF MULTIPLE SWITCHBOARD. NO ANSWERING JACKS.

complete a connection between the line of any of the group of subscribers directly served by her and the line of any other subscriber connected to the exchange in one operation. This method does away with the transfer of calls from one switchboard to another, and makes the work of establishing connections much simpler and quicker than it was with the original divided switchboards.

In a multiple switchboard each section is, as a rule, somewhat less than 6 feet long, and contains three operators' positions. In each section there is a connecting spring jack for every line in the exchange. Therefore, as regards the vertical part of the switchboard, each section is a duplicate or multiple of every other; hence the name of multiple

FIG. 24.



SERIES MULTIPLE SWITCHBOARD.

switchboard. In the earliest forms of multiple switchboard, only one set of jacks was provided at each section, but it was quickly found that it was a considerable strain on the operator to trace the relation between an indicator and any one of a thousand or more spring jacks. This arrangement was therefore modified by the introduction at each section of a certain number of special spring jacks, which form the terminals of the lines to be served at that section. These were called "answering jacks," as they were used exclusively for answering the calls of subscribers. There being at each section, or at each operator's position, a small group of signals and a small group of answering jacks, it was comparatively a simple matter for the operator to trace the relation, by means of the corresponding numbers, between any signal and any answering jack.

The horizontal portion of the switchboard, generally termed the key-board, serves as a support for the plugs and cords by means of which the operator effects temporary connection between the lines, and for the keys and switches by means of which the operator connects her own telephone set to the line of any subscriber as may be required, and connects the ringing machine to a line on which it is desired to signal for the attention of a subscriber. In modern types of switchboard some of the signals are also placed in the key-board.

At first the multiple switchboard was thought to be too complicated, and it was some little time before it was put into practical use on any scale. A very short experience, however, showed it to be so superior in ease of manipulation, in accuracy, and in speed, that within a very few years the multiple switchboard displaced all types of transfer and divided switchboards. Of late years there has been a tendency to return to a divided type of switchboard in which the calls of subscribers are answered at one switchboard and completed at another; but, as will be described later, these special switchboards are used to cope with special conditions which a close study of the telephone traffic of large cities reveals, or else are due to theories which do not always turn out well in practice.

In tracing the evolution of the multiple switchboard, we find that it has gone through numerous modifications, arising from improvements both in mechanical and electrical conditions. In the early days of the multiple switchboard a switchboard for a thousand lines was considered a large piece of work. For many years a switchboard for 5,000 lines was the largest in existence. At that time, owing to the size of the spring jacks and the relatively small number of lines which could be worked under the prevailing methods of operation at one section, such a switchboard consisted of some 44 sections. With improvements in manufacture, and with improvements in methods of signalling and methods of operating, it has become possible to work many more lines from one operator's position and to put many more spring jacks in one section. Consequently, switchboards for 10,000 lines are now made of practically the same length as a switchboard for 5,000 lines would have occupied a few years ago. It is practicable, indeed, to build multiple switchboards for even much larger numbers of lines than 10,000, and there are several multiple switchboards in existence or building designed to accommodate from 15,000 to 18,000 lines.

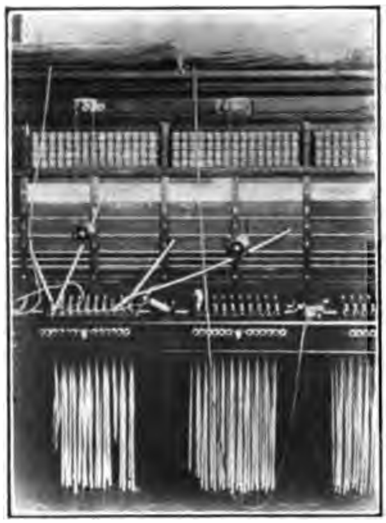
As described above, the separation of the two

springs of the spring jack when the plug was inserted, was utilised in the early switchboards for the temporary disconnection of the indicator from the line during the time that a subscriber's line was placed in connection with another. In the early telephone exchanges all the lines were single wire and the circuit through the switchboard was also a single wire circuit, the spring jacks being inserted in the line in series, the line going into one jack, so to speak, by one spring and coming out by the other, the pressure between the two springs maintaining a contact which was broken by the insertion of the plug. This gave a ready means of disconnecting the line signal whenever the line was in use, and of automatically restoring the signal to connection with the line when the plug was withdrawn. A few years' experience showed that it was necessary for good service to make all the lines of a city telephone system metallic circuit, as it was found that single wire circuits connected to earth picked up so many foreign currents by leakage and induction that communication was often impossible. Making the lines metallic circuit involved making the switchboard circuits also metallic. In the earliest metallic circuit switchboards the arrangement of the jacks in series was retained, but it was found that in large switchboards the series jack gave rise to many difficulties. With a large number of jacks in series on one line—and, as has been shown, there might be in a large switchboard as many as 45 jacks in each line—a sufficient number of bad contacts, due either to the presence of dust or to separation of the springs of the jacks, might arise to cause bad service. Also, in a large switchboard there would often be an unbalanced loop of wire running through the switchboard and back to the jack at which the connection was effected, which would be sufficient to throw the circuit out of balance and cause cross-talk or inductive action between one circuit and another.

In the single-wire switchboard the clearing-out indicator, which was temporarily associated with two lines in use by means of the connecting cord, was legged on to earth. In the metallic circuit switchboard it became necessary to bridge the clearing-out indicator between the two strands of the connecting cord, using an indicator coil of high resistance and impedance so as not to shunt the telephonic currents. The use of the clearing-out drop bridged across the line led naturally to the idea of bridging the line signal across the line and leaving it permanently connected to the line instead of temporarily disconnecting it every time a line was connected to another.

These inventions led to a greatly improved type of switchboard, in which much of the work was made automatic. This type of switchboard is generally known as the "bridging" or "branching" switchboard, and its outward distinction from the type of switchboard which preceded it arose from the fact that the various indicators were made

FIG. 25.



BRIDGING SWITCHBOARD WITH SELF-RESTORING DROPS.

self-restoring, thus saving the operator the work of restoring the indicator shutter every time that a signal was given by a subscriber. The self-restoring indicator marked a distinct advance in telephone switchboard operating, and the bridging method of connecting the indicators to the circuits marked a distinct advance in the electrical design of the telephone switchboard.

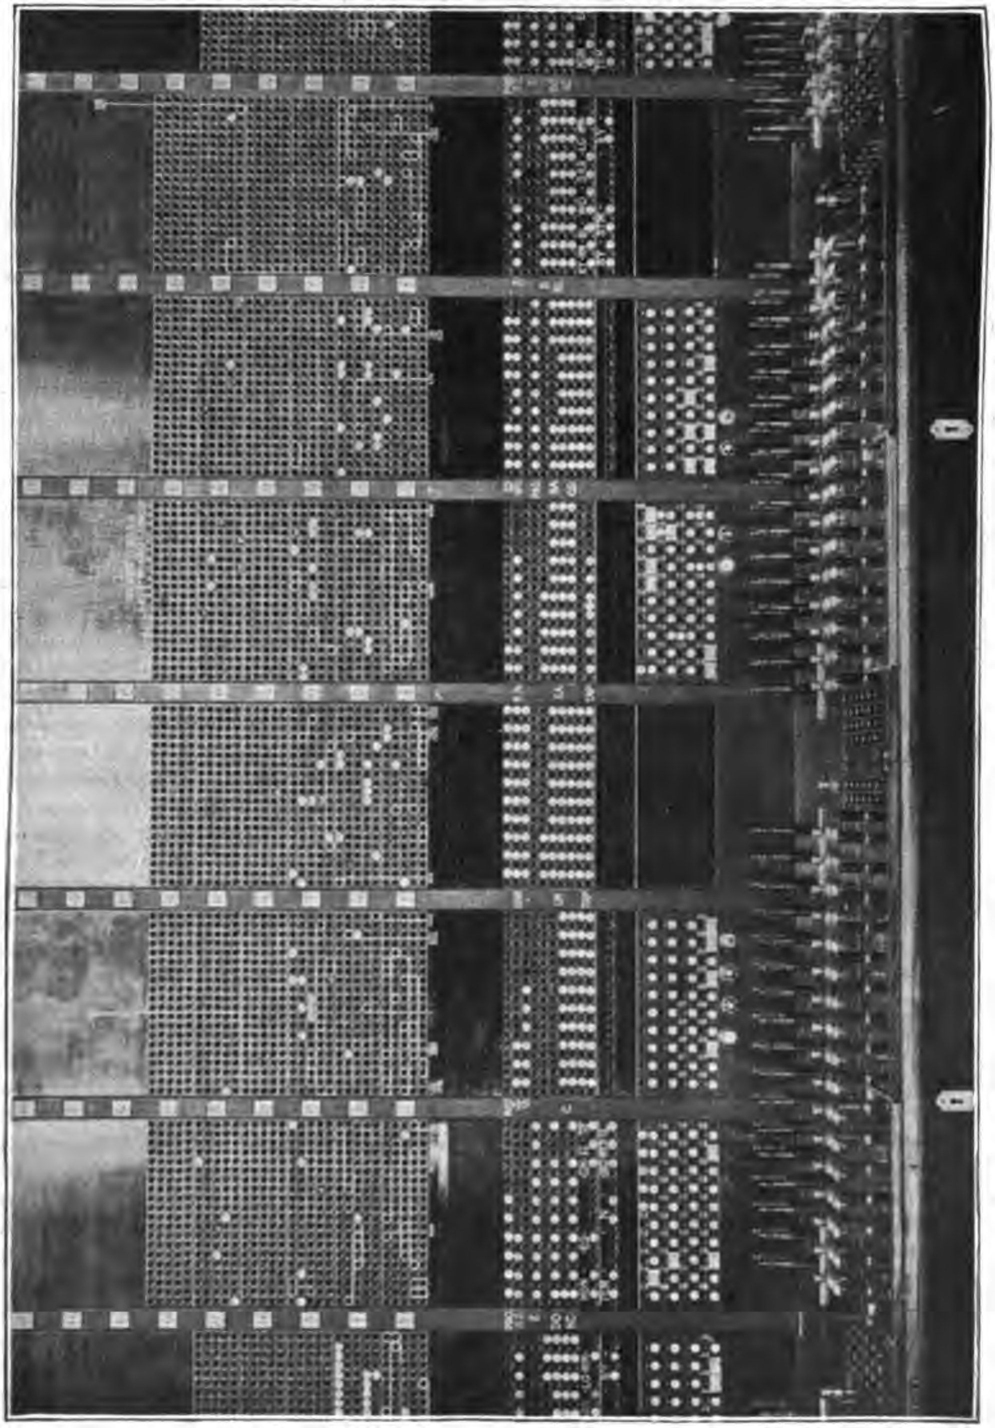
In the bridging switchboard the circuit throughout the board is a balanced metallic circuit, free from series contacts. Each line is joined to one spring of each spring jack, and different parts of the connecting plug, when inserted in the spring jack, make contact with each of these springs. The line signal is, as has already been said, bridged permanently across the line, and the indicator shutter is controlled by a restoring magnet inserted in a third wire which is local to the switchboard.

This wire is connected to a source of current and to contacts in the spring jack, so arranged that when the plug is inserted in answer to a call the circuit is completed and the restoring magnet energised, thus restoring the indicator shutter to its normal position. The clearing-out indicator is similarly made self-restoring, the restoring magnet in this case being operated by a depression of the listening key.

The self-restoring switchboard indicator, which was brought out in the early nineties, was largely copied by means of mechanically restored indicators, in which the indicator shutter was replaced to its normal position by the insertion of the plug in the spring jack or by the replacement of the plug on the cord shelf. It is of course easy to make either of these operations perform a second operation at the same time, by means of causing the plug to actuate a lever or cam on entering the jack or by causing it to trip a lever connected to a shutter when it drops back into its place on the cord shelf. These mechanical restoring devices, however, involve the close association of the indicator and the spring jack or of the indicator and the plug socket on the cord shelf, methods of construction which other requirements of a telephone switchboard make it not always advantageous to adopt. Consequently, these mechanically restoring devices are seldom used except on switchboards of small size.

We now come to the era of lamp signals and common battery working. From the very earliest days of telephone exchange working it has been the object of telephone engineers to do away with the use of individual batteries at the subscribers' stations. The cost of the upkeep of these batteries is very great, and their unequal performance renders it almost impossible, except at enormous expense, to maintain in a large system a high average efficiency of service. There have been many methods and devices tried with the object of working all the telephones of an exchange from one central battery, and there have been various methods tried, from the very earliest days of telephone exchange working, of making the signals required at the beginning and end of a conversation automatic, that is, making the natural acts of taking the telephone off the hook and replacing it control the necessary signals at the exchange. The storage battery at first displaced the collections of primary batteries originally used for energising the operators' transmitters at the exchange, and later was used at subscribers' stations instead of primary batteries, the storage batteries being kept constantly charged over the actual subscriber's line. In connection with this method of battery supply automatic signalling was adopted, first with electro-magnetic signals, and later with lamps controlled by relays. The gradual evolution of all these methods finally resulted in the complete common battery system, in which a storage battery at the exchange supplied the energy for all the telephones in the system as well as for operating all the various signals required in the switchboard. This system was worked out experimentally about 1894, and was then tried in small installations in America. With the experience gained in these trial installations improvements were made and the apparatus was sufficiently standardised to enable the system to be put into commercial operation about three years later. The great improvement which this method makes both in the economy and efficiency of telephone service has now made it the standard system of operating telephone exchanges, and practically no new work is now done on any other lines.

The first appearance of a power plant in a telephone exchange (Fig. 27, p. 1080) was in connection with the bridging switchboard just described. In the original switchboards there was placed a hand magneto generator at each operator's position, to enable the operators to ring the bells at subscribers' stations. These individual generators were very quickly replaced by a machine-driven generator, from which a supply circuit was carried along the switchboard and made available at each operator's position by means of ringing keys. This was the beginning of the telephone exchange power plant. To operate the signals and circuits of the bridging switchboard a more elaborate power plant was required, comprising storage cells with a generator to charge them, and about this time there was evolved the motor generator for supplying ringing current. In the common battery system the power plant reaches much larger proportions, as it is called upon to do a much greater variety of work than its predecessor. It replaces the batteries and magneto generators at all the telephones of the system, as current is taken from the one central plant to operate all the telephone transmittors in the system as well as all the signals in the switchboard. The source of current supply is a battery of eleven large storage cells which are charged periodically by a motor-driven



COMMON BATTERY SWITCHBOA

generator of 30 kilowatts capacity. The ringing machines, also motor driven, have been greatly improved and elaborated, and supply not only alternating current for ringing purposes, but also current of special characteristics for giving the distinctive signals required in the varied operations of a large telephone service. For example, an operator at a distant exchange informs the operator at an originating exchange that a line wanted in the distant exchange is "engaged" not by word of mouth, as was formerly the practice, but by means of an electrical signal which gives a distinctive hum or buz on the wire. In the same way other forms of current, giving distinctive pulsations or vibrations, are used for other special signals between operator and operator.

FIG. 27.

TERMINAL ROOM OF MODERN EXCHANGE, SHOWING POWER PLANT.

In the common battery switchboard, practically all of the signals employed are lamps, instead of indicators, and this gives the face of the switchboard an entirely different appearance from that of a switchboard of the older type, in which indicators were used as signals. The lamp has so many advantages over the electro-magnetic indicator as a telephone switchboard signal that, although the early lamps and the relays for controlling them gave rise to much trouble, continuous efforts were made to reduce them to a practical and reliable state, with such success that within a very few years thoroughly efficient telephone relays and lamps were produced. This says a good deal for the telephone manufacturers, as the telephone lamp is necessarily extremely small, and works under much more difficult conditions than the ordinary electric lamp, while the telephone relay to be really useful must work with certainty, often on a comparatively small margin of current, and often a very large number of times each day. That the difficulties in the production of reliable lamp signals and relays have been completely overcome is clear from the fact that telephone lamps and relays are now in use by the million, and that the telephone service of practically every city in America, and of many large cities in Europe, is conducted entirely by means of relays and lamps.

The lamp signal is not only more effective as a signal than the indicator, but it has the great advantage of being automatic or self-effacing. It is also extremely compact, and as it has no working parts it may be placed in any position on the switchboard, vertically, horizontally, or at an angle; an indicator could naturally be placed only in one position. As a result of these qualities of the lamp signal, we see that it has been possible to effect many improvements in the telephone switchboard, which make greatly for its efficiency and economy. In the original series switchboard it was necessary to place the signals within reach of the operator, as the operator had to restore the indicator shutters by hand. In large switchboards this involved the use of a trough behind the keyboard (in which the indicators were placed), to permit the top rows of the multiple jacks to be within the reach of the operators. In the bridging switchboard, as the indicators were self-restoring, they were placed at the top of the switchboard, thus effecting a considerable gain in space in the face of the switchboard available for multiple jacks. But in both these arrangements it was necessary for the operator to trace the relation between any given indicator and its corresponding spring jack or cord, and this involved a certain mental effort. The compactness and simplicity of the lamp signal enabled it to be placed immediately adjacent to the particular spring jack or cord to which it is related. Thus, in the common battery switchboard we find each signal immediately above or below its corresponding answering jack, and each cord signal immediately alongside its corresponding cord. This arrangement makes greatly not only for the compactness of the switchboard but for accuracy in operating, as there is never any doubt as to the meaning of a signal or the particular part of the switchboard which has to be manipulated in response

to a signal. The work of the operator is therefore greatly simplified and becomes correspondingly more rapid and more accurate.

In the operation of the common battery switchboard it will be seen that the working has become more automatic than in the form which immediately preceded it. A very great improvement has also been introduced in the provision of automatic means for supervising the state of two subscribers' lines when connected for conversation. In the older system the clearing out signal was dependent on the memory of the subscriber; the subscriber had to turn his generator to actuate the signal and it has been the invariable experience of telephone managers that many subscribers habitually forget or neglect to perform this operation. This would naturally result in many connections being left up longer than is necessary, as the operator, not receiving a signal to disconnect, would only after a time discover that the subscribers had finished talking and had failed to give the signal. In the common battery system this state of affairs is done away with altogether, as there is a lamp signal on each of the cords used to connect subscribers' lines, and the operation of each signal is governed by the condition of the corresponding subscriber's telephone. If the telephone is on the rest the cord signal lamp —or supervisory lamp, as it is termed—is alight, and if the telephone is off the rest the supervisory signal is extinguished. The presence of these two signals enables the operator to see at a glance the state of any connection which is up at her position. When she connects a subscriber wanted in response to another subscriber's call, the supervisory lamp on the connecting cord lights as soon as she inserts the plug in the multiple jack and remains alight until the called subscriber answers. When the called subscriber takes his telephone off the hook the supervisory lamp goes out, and this notifies the operator that the called subscriber has answered. From that point the supervisory lamps will continue to keep the operator informed of the state of the connection. If one subscriber hangs up, the corresponding lamp lights, but the other lamp, remaining extinguished, indicates to the operator that the corresponding subscriber is "holding the line." When both subscribers hang up, both supervisory lamps light, and this is a positive indication to the operator that the two subscribers have finished conversation and wish the lines to be disconnected. The operator then immediately takes down the connection without listening in. This automatic supervision and positive disconnection signal are very valuable qualities in the common battery method of working. Under the older method a large amount of the operator's time was devoted to supervising each connection in order to ascertain whether the two subscribers got together satisfactorily, and whether they had finished conversation and neglected to give the disconnection signal. All that work is now done away with, and the operator, can follow the movements of the subscribers by means of the two lamps practically as effectively as if she were watching the motions of the actual persons using the two distant telephones. Apart from the increased efficiency which this method gives to the operator, it also largely increases the efficiency of the service by reducing the amount of time during which the subscribers' lines are connected together uselessly, thus reducing the "engaged" trouble, which is one of the principal difficulties and sources of friction in all large city telephone systems.

As a result of these various improvements it may be said that the telephone switchboard of to-day is at least twice as efficient and economical as the telephone switchboard of ten years ago. It gives a far more regular, accurate and speedy service to the subscribers, and it performs its work with much less strain on the operators. The apparatus required to effect these results is, of course, complicated and extensive. Every line signal, for example, is controlled by two relays, one which causes the lamp to light when the subscriber takes his telephone off the hook, and one, termed the cut-off relay, which automatically extinguishes the lamp when the operator plugs into the answering jack. Also, as touched on above, the power plant of the modern telephone exchange is quite an important installation, but it must be remembered that these appliances, all concentrated in one department under expert supervision, take the place of thousands of individual appliances which were formerly scattered among the individual subscribers' stations. The relays and power plant of the exchange take the place of the myriads of generators and primary batteries formerly used at the outer ends of the lines. Therefore the subscriber's instrument, the appliance which is in the hands of the public, and repeated in tens of thousands of different premises, has become extremely simplified, and consists now only of transmitter, receiver, bell, and the neces-

sary switch-hook to change the circuit from the bell to the telephone; and this great gain of simplicity in the instrument which has to be repeated many thousands of times more than compensates for the additional complication of apparatus at the exchange end.

TELEPHONE BUILDINGS.

A very important part of the modern city telephone plant is the central office building. It is necessary that a telephone exchange building should be of special construction, both because of the necessity for the utmost precaution to prevent fire and because of the very special nature of the plant to be contained by the building and of the accommodation to be provided. The telephone exchange building, to begin with, has to serve as an anchorage or point of concentration for the underground cable plant, and its site has to be chosen not with regard to the most convenient or most economical position as dictated by property considerations, but with regard to the most convenient and economical position as dictated by telephone conditions; that is, the building should be placed at the economical telephone centre of the area to be served, and this fact often necessitates the construction of a building of an entirely different character from the neighbouring buildings in the same locality. For these reasons it is necessary to consider the telephone building as a part of the plant, and in the long run satisfactory results will not be obtained unless this is recognised and special telephone buildings, designed exclusively for the accommodation of telephone plant, are made an integral part of city telephone systems.

The accommodation which a telephone building has to provide may be divided into three general parts—the terminal room, providing for the termination of the underground cables and their junction to the switchboard wires and the power plant; the operating room, providing for the accommodation of the switchboards; and the operators' quarters, consisting of cloak-rooms, dining-rooms, reading-room, etc. In the older buildings it was the practice to terminate the underground cables in air-tight cable heads supported on racks placed in the basement or cellar and to effect the junction with the switchboard wires by means of house cables extended from the cable heads to the distributing frame. The modern practice is to abolish the cable head and by means of what is known as a "pot-head joint" to extend the underground cable conductors direct to the distributing frame. The distributing frame is a flexible link joining the outside wires to the switchboard wires. Owing to the numerous changes which constantly occur in the distribution of the various wires in a telephone system it is necessary to have a ready means of changing the relations between the switchboard wires and the outside wires. This is afforded by the main distributing frame, a long rack or framework on which are terminated in regular order on one side all the conductors of the cable plant, and in regular order on the other side all the wires of the switchboard plant. By means of pairs of wires termed "cross connecting" or "jumper" wires, which are passed through the centre of the rack, any pair of outside conductors may be joined to any pair of switchboard conductors as desired.

A second frame-work of the same kind is termed the "intermediate distributing frame,"

FIG. 28.

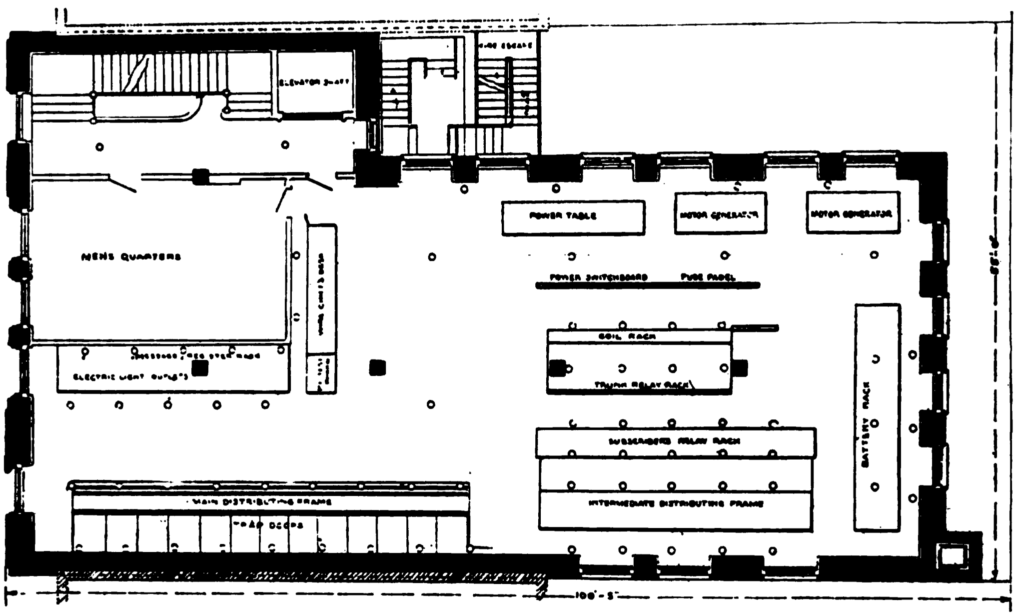
TERMINAL ROOM OF MODERN EXCHANGE, SHOWING RELAY RACKS, DISTRIBUTING FRAMES, AND TESTING OUTFIT.

and this affords a means for varying the distribution of the line signals and answering jacks in the switchboard. It frequently becomes necessary, in order to equalise the load at the various operators' positions in the switchboard, to vary the number of lines terminating at different positions. The intermediate distributing frame forms a flexible link between the answering jacks and line signals and the multiple circuits which run through the switchboard. By varying the connections at the intermediate distributing

frame the actual terminal of a subscriber's line can be removed from one part of the switchboard to another.

These two distributing frames, together with the relay racks carrying the various line and cut-off relays, and the whole of the power plant, consisting of duplicate sets of charging generators and ringing machines, are now generally placed all in one department, and usually occupy the whole of one floor. A floor of similar dimensions is occupied by the cloak rooms, dining-room, and resting rooms for the operators, and the top floor,

FIG. 29.

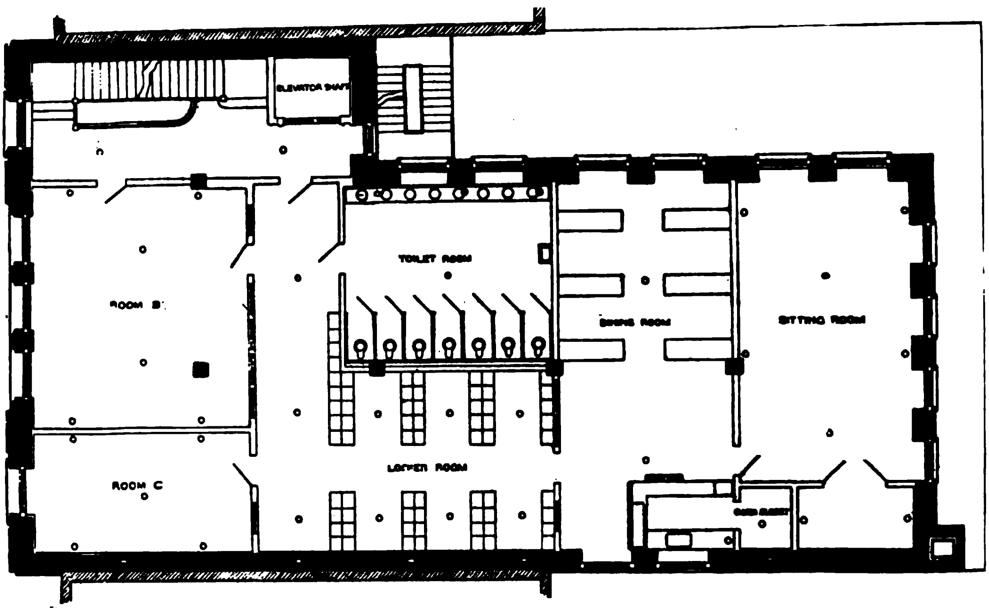


MODERN TELEPHONE BUILDING. Floor Plan of Terminal Room.

where the condition of light and air are the best, serves as the operating room. The ideal conditions required for the telephone operating room are good light and ventilation and free floor space of such dimensions that the switchboard may be carried in a continuous line so as to avoid sharp angles or end sections, which are uneconomical for the reason that they occupy switchboard space without giving corresponding working positions. The floor plans of a modern telephone exchange building in New York (Figs. 29, 30, 31) illustrate the arrangement of a typical city telephone building.

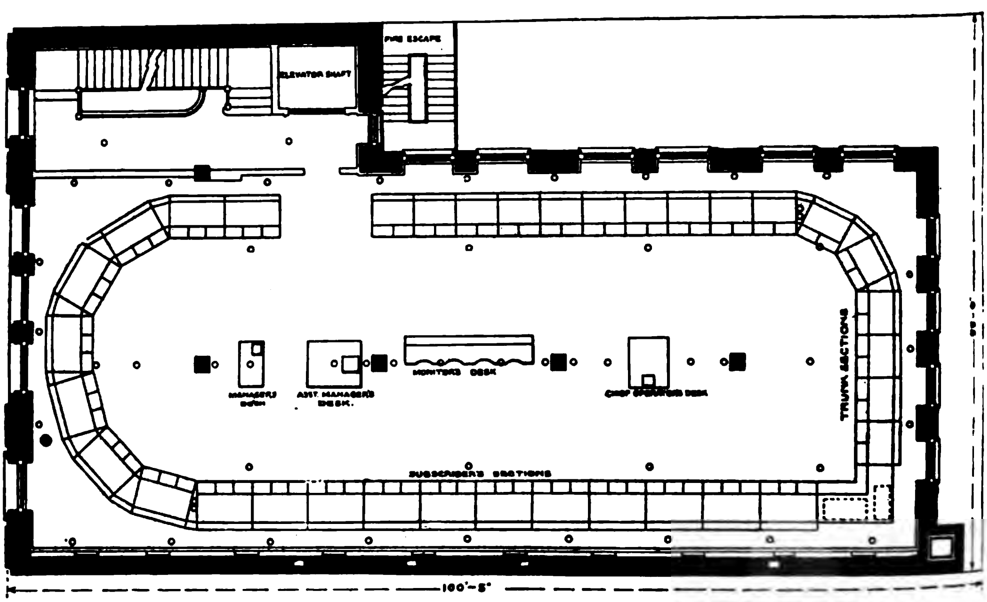
While, as pointed out above, the great improvements made of recent years in all parts of the telephone switchboard enable many more lines to be worked from one exchange than was practicable ten years ago, the best experience shows that it is not advisable to build in large cities exchanges of more than 10,000 lines capacity. This is not universally admitted, however, and there have been several schemes devised to permit of much larger numbers of lines being worked from one exchange. The capacity of the standard multiple switchboard is about 15,000 lines—that is to say, with switchboards arranged with the answering jacks in the multiple sections there is space for about 15,000 multiple jacks in a section of such a size that all parts of it are within reasonably convenient reach of the operators. If the answering jacks and line signals be placed somewhere else than at the multiple sections, space is freed for further multiple jacks, and the capacity of the switchboard can be increased. If the switchboard be divided into several parts, and the subscriber be provided with means for selectively signalling the several different parts, according to the number with which he wishes to be connected, there is practically no limit to the number of lines which may be connected to one exchange. Both these methods of increasing the capacity of a single exchange are in actual use. In the new exchanges

FIG. 30.



MODERN TELEPHONE BUILDING. Floor Plan of Operators' Quarter.

FIG. 31.



MODERN TELEPHONE BUILDING. Floor Plan of Operating Room.

built at Moscow and Warsaw by L. M. Ericsson and Co., of Stockholm, the line signals and answering jacks are all at special answering switchboards, and the multiple switchboard is devoted to multiple jacks exclusively. By the use of a very small multiple jack, and by having the whole vertical face of the board available for multiple jacks, it is expected to obtain an ultimate capacity of some 30,000 lines in the one switchboard. In the method of operating, the operator at the answering board, on receiving a call from a subscriber, plugs the calling line through to an operator at the multiple board. This second operator then answers the call and completes it in the usual way. The connecting lines between the two switchboards are equipped with lamp signals which automatically indicate to the answering operators which of the connecting operators are free to receive a call, and to the connecting operators the particular cord and plug to which a call has been transferred by one of the answering operators. The answering operators do no talking at all, but simply plug the lines of calling subscribers through to operators at the multiple board who are free to handle the calls. When a connection is taken down at the multiple board a lamp signal on the connecting cord at the answering board automatically signals the fact to the answering operator, who in turn completes the disconnection of the line indicated. A similar system of working is in use at the Stockholm Exchange of the Swedish State telephone system.

The other system referred to of increasing the capacity of an exchange above the limits of a standard multiple switchboard is what is what is known as the "divided multiple." This was introduced in America some ten years ago, and although it is disappearing from American practice, this method has been adopted in the new municipal exchange at St. Petersburg. The principle is to divide the switchboard into several portions, each portion containing multiple jacks for a certain number of subscribers. For example, board No. 1 would contain lines for subscribers from No. 1 to No. 20,000. Board No. 2 would contain lines for subscribers from No. 20,001 to 40,000, and so on. Each subscriber is provided with a line signal and an answering jack at each of the divisions of the switchboard, and it devolves upon the calling subscriber to actuate the particular line signal in the division of the board which serves the multiple line of the subscriber to whom he wishes to be connected. One of the radical defects of this system is that it robs the subscriber's instrument of its simplicity. The subscriber's instrument must be provided with two or more buttons in order that the subscriber may signal the particular division of the switchboard which can handle his connection. This provision of several different signalling buttons to be operated at the will of the user of the telephone gives the means of making erroneous calls, and it is common experience that when means for committing errors are put in the hands of the public many errors are committed. The preponderance of telephone experience regards unfavourably any system which puts into the hands of the general public an instrument requiring specific manœuvres for the proper working of the service.

Automatic Exchanges.

There have been devised numerous methods whereby telephone lines may be switched together by means of electro-mechanical apparatus operated from the subscribers' telephones. The general principle of these systems is a selective switch controlled by a selector or impulse transmitter attached to the subscriber's instrument. The broad result is that the operation of the service is transferred from the operator to the subscriber, and to effect this result there is brought into use apparatus of considerable complication at both ends of the system.

That the so-called automatic exchange will ever entirely displace the so-called manual exchange appears very unlikely. There are several automatic exchanges in practical and successful operation, but in all cases these automatic exchanges are second or additional telephone systems in the towns in which they operate, and they do not by any means carry the whole telephone traffic of the area which they serve. In the telephone service of any large city or group of towns the possible range of selection of telephone calls is so great that it seems impracticable for any purely mechanical system to cope with it.

Thus, in the automatic systems the human operator quickly appears to handle suburban and long distance calls. It is also necessary to have an operator to handle inquiry calls, and for these various reasons the mechanical system soon ceases to be purely mechanical. It is hardly realised by those who term the mechanical switch systems automatic, how largely automatic the standard common

battery system really is, but a detailed inspection of the working of the standard common battery system shows that with the exception of the actual selection of the numbers and insertion and withdrawal of the connecting plugs almost all the operations are automatic.

The subscriber automatically signals the exchange by lifting off and replacing the telephone and the signals thus automatically set are automatically re-set by the insertion and withdrawal of the plugs at the exchange. The signals on the junction lines connecting one exchange with another are similarly automatically set and re-set, and the ringing is done automatically after a single depression of a button. Human labour and human intelligence are employed in that part of the work where, under the existing conditions, it would seem that they can best be employed, namely in the prompt selection of individual numbers from the immense range of numbers which exist in the modern city telephone system. It seems likely that in the future development of the telephone system the operator will never entirely be done away with in favour of the machine, but that the machine—*i.e.*, the automatic device, of whatever character it may be—will be more and more extensively employed, but always rather under the control of the expert operator than of the inexpert member of the public.

AUSTRALIAN MANUFACTURES.*

Although in the infancy of its national existence, and having to struggle with the disadvantage of possessing only a limited population in a territory capable of supporting as many millions as are to be found in Continental Europe, and yet have plenty of country to spare, the Commonwealth can boast that in addition to its remarkable pastoral, agricultural, and mining development, it is furnishing a large and remunerative field for manufacturing enterprise. Already, according to official statistics, the amount of capital employed in Australian manufacturing industries is estimated at something like £60,400,124; of which £19,484,122 represents the value of land, buildings, &c.; £20,357,002, machinery and plant; and £20,559,000, cash and sundries. The figures at the close of the present year will show a considerable advance upon those quoted. The various industries cover a wide field, and include those treating raw pastoral and agricultural materials; animal, vegetable, and other oils and fats; processes in stone, clay, glass, &c.; working in wood, metal-works, machinery, &c.; connected with food, drink, &c.; clothing and textile fabrics and materials; books, paper, printing, engraving, &c.; musical instruments, arms and explosives; vehicles and fittings; harness, saddlery, &c.; ship and boat-building, &c.; furniture, bedding, and upholstery; drugs, chemicals, and by-products; surgical and other scientific instruments; jewellery, time-pieces, and plated ware; heat, light, and power; leather ware; and others of a miscellaneous character. The number of people, male and female, employed on the various industries is estimated at 196,424; of whom 86,284 are engaged in producing commodities coming into competition with imported goods. The difference between the value of the materials, fuel, &c., employed, and the total value of the output represents the real value of manufacturing production. At the close of 1903 the figures were £28,528,000; a large amount considering that the bulk of the production was intended for local consumption amongst a limited population. The average weekly rates of wages for men in New South Wales ranged from £2 8s. 8d. to £1 0s. 10d., and in Victoria from £2 4s. 11d. to £1 1s. 11d. As a large number of lads are employed, the wages of the men are considerably higher, but it is difficult to eliminate the juvenile element from the calculation. Taking several of the leading industries, it is found that 1,592 hands are engaged in the manufacture of soap and candles; 7,859 in the production of bricks, tiles, pottery, earthen and glassware, &c.; 36,376 in the manufacture of agricultural implements, brass and copper goods, cutlery, galvanised iron, engineering and ironworks, foundries, lead mills, smelting works, railway and tramway workshops, tinsmithing, wire-working, and other metal works; 12,564 in boot and shoe making; 31,691 in the manufacture of male and female articles of clothing; and 5,440 in the production of furniture, bedding, &c. Numerous other manufacturing industries might be enumerated, but the foregoing will suffice to indicate their general character. There are nearly 12,000 industrial establishments of all kinds, employing close upon 200,000 hands, with a steadily increasing tendency in the number of both. Generally speaking, the character of the locally-made commodities is fully equal to that of the imported goods with which they come into competition, the great disadvantage under which Australian manufacturers labour consisting in the fact that the average rates of wages are higher and the hours of labour fewer than in oversea countries. In Victoria the system of sweating is prohibited by law, and in New South Wales it is checked by the operation of the State Industrial Arbitration Act. In articles demanding the employment of artistic taste there has been a rapid advance, a result of the increasing spread of technical education, many of the workmen students in the technical colleges producing specimens of their handicraft fully equal in beauty of design and delicacy of execution to anything of the kind met with in Europe and America.

* Communicated by Mr. John Plummer, of Sydney.

THE EXPORT TRADE OF THE UNITED STATES.

Exports of manufactures from the United States in the fiscal year ended June 30, 1905, were not only the largest on record, but are in excess of the combined exports of all articles in the centennial year 1876, and nearly twenty-eight millions sterling more than the total imports and exports of the country at the end of the Civil War. Figures just compiled by the United States Bureau of Statistics show that the exports of manufactures in the year just ended amounted to £113,254,000, as against £94,253,000 in the preceding year, £90,386,000 in 1900, and £38,249,000 in 1895. The growth in exports of manufactures far exceed the growth of population, or the growth in commerce as a whole. This is apparent from an examination of the following Table, showing the population, commerce, and exports of manufactures of the United States in 1800, 1876, and 1905, and the percentage of increase in each since 1800 and 1876, the beginning of the greatest era in American development :—

Years.	Population.	Commerce (Imports and Exports of Merchandise).	Exports of Domestic Manufactures.
		£	£
1800	5,308,483	31,746,000	510,000
1876	45,137,000	208,567,000	20,935,000
1905	83,145,000	547,182,000	113,254,000
Per cent. of Increase.			
1800-1876	750	517	3·930
1876-1905	81	63	441

An examination of the statistics of exports of domestic manufactures, especially in recent years, by articles and countries of destination, shows that about 30 manufactured articles were exported during 1905, with value in excess of £208,000 each, and that of these articles, all except seven showed an increase as compared with exports of 1904. Iron and steel manufactures supply about one-fourth of the manufactured articles exported from the United States, the total in 1905 having been £28,068,000, as against £23,322,000, in the preceding year, an increase of nearly five millions sterling. Steel rails showed an increase of £1,250,000, chiefly in shipments to Canada, South America, Mexico, the West Indies, Japan, and the eastern countries, in several of which, railway development is proceeding at a rapid rate. Machinery also showed an increase in 1905 of more than £1,250 000 over 1904. A conspicuous feature, however, is the large increase in exports of locomotives to Japan, 151 engines having been sent thither in 1905 as against 74 in the previous year. Mexico and Argentina increased their purchases of American sewing machines, while Japan increased her purchases of electrical machinery and builders' hardware, each in a substantial degree. Copper manufactures, consisting largely of pigs and bars, form the item of second importance in the United States exports of manufactures, the total being £17,963,000 in 1905, as compared with £11,905,000 in the preceding year. This growth of six millions sterling in a single year is accounted for by an increase in exports to China, the United Kingdom, France, Germany, the Netherlands, and Russia. Refined mineral oil ranks third in the exports of manufactures, the total being £14,996,000, against £14,948,000 in the preceding year. Owing to the fall in prices the value remained practically stationary, despite the fact that the quantity increased from 847 million gallons in 1904 to 951 millions in 1905. The countries to which the largest exportations were made were—the United Kingdon 221 million gallons, Germany 342 millions, Netherlands 117 millions, China 90 millions, Belgium 46 millions, British East Indies and Japan each about 30 millions, Italy nearly 29 millions, and France 27 millions. Cotton manufactures present one of the striking features of the year's export trade, having advanced from £4,650,000 in 1904 to £10,347,000 in the year just ended. To China there was an increase of about 400 million yards over last year's exportation, and the value of American cotton cloth exported to that country increased from £830,000 in 1904 to £5,780,000 in 1905. Leather and its manufactures, fourth in importance in the list of manufactured articles exported, showed an increase of £830,000, the total in 1905 having been £7,916,000, as compared with £7,020,000 in the preceding year. In this class of goods Japan is credited with the chief increase. Other important articles exported from the United States in the year ended 30th June, 1905, were agricultural implements, chemicals, dyes, drugs, &c., wood manufactures, cars, carriages and vehicles, paper and manufactures thereof, and india-rubber manufactures. The following Table shows the exports of the manufactures of the United States, and the total exports from that country, decennially from 1870 to 1900, and especially from that year up to the present time :—

Years (ended 30th June).	Exports of United States Manufactures.	Total Exports of Merchandise
	£	£
1870	14,225,000	81,828,000
1880	21,428,000	174,091,000
1890	31,479,000	178,714,000
1900	90,386,000	290,517,000
1901	85,611,000	309,951,000
1902	84,092,000	287,888,000
1903	86,901,000	295,862,000
1904	94,253,000	304,339,000
1905	113,254,000	316,367,000

HOME INDUSTRIES.

The Neglect of Forestry.—In discussing the Cottage Exhibition at Letchworth it has been said that wooden structures have much to recommend them, and that it is regrettable that more wooden cottages are not built in the rural districts. But it may be doubted whether under present circumstances wood would often prove much cheaper than brick. The wood would have to be of mature growth, and free from sap, and that is expensive whether got from abroad or at home. As to home-grown timber it is quite as costly as foreign, and much less suitable, being reared so badly that boards and scantlings cut from it are more often than not full of knots, shakes, and twists. And they in turn are the result of the general ignorance of forestry. In 1888-89 a Select Committee sat to inquire into the condition of forestry in Great Britain, the possibility of improvement, and the necessity for the provision of better means of education. Various recommendations were made but nothing came of them, and when the Committee of 1902 was appointed it started very much at the same point as did the earlier Committee. It is true that now forestry is one of the subjects of which the Board of Agriculture has charge, and that department is doing good work in relation to it, but the management of existing forests still leaves much to be desired, and little is being done to extend the forest area.

The Financial Aspect of Afforestation.—There is in these islands a very large area of waste, heather, and rough pasture, or land out of cultivation, on which afforestation might be profitably undertaken. It has been said that our soil and climate are unsuited to the growing of woods, but this opinion may well be traversed, nor is it that of foreign experts. In their opinion our soil and climate are very favourable, and the magnificent isolated trees to be seen in parks and on road sides proves this. The suggestion that we have too little sunshine will not bear examination. We have at least as much as Norway, Sweden, Finland, and the southern and eastern shores of the Baltic, whence much of our imported timber comes. As to the financial aspect, the available data with regard to returns suffer under two great drawbacks. First, the greater part of the areas under forest in this country do not produce as much timber as they would if properly managed, and secondly, the returns available are mostly a little haphazard. But it may safely be said that, placed suitably, properly managed woodland pays. Mr. Arthur Vernon, whose experience of estates in which there is considerable woodlands is very great, told the Committee of 1902 that the best woods can be made to return £2 an acre for a long succession of years, and he instanced Hughenden, of which he is the agent. The woods on the property are small, covering about 200 acres only, but they have produced an average of £2 per acre per annum for a great number of years. Deduct 15 per cent. as the cost of felling and selling the timber, the cost of the woodmen, and other expenses, and the net return works out at about 27s. an acre. It may be said that this large profit is due to High Wycombe being the centre of the chair trade. No doubt it has much to do with it. The nearness of the raw article created the trade and the demand, and easy means of supplying it enhances the profit. But what they have done at Hughenden might be done in many other parts of the country. There was bad land on the estate, cold, hilly, and exposed. For agricultural purposes it was not worth more than 10s. an acre. The owner put it into wood, and nearly trebled its value, besides creating a home industry, giving work to many. Granted that the woodland profit in the Chiltern districts is exceptional there is plenty of poor grazing land suitable for afforestation. Much of it would be more profitable in growing timber than in agriculture. A good deal of it is grazing pasture let at 9d. to 1s. 6d. an acre, and even under the worst conditions of forestry something more could be got out of it than that.

The Area Suitable to Afforestation.—What may be called the waste land in the United Kingdom is very large. Its area (excluding mountain and heath) in England is given in the agricultural returns at 5,396,250 acres, in Wales at 669,609 acres, in Scotland at 5,028,833 acres, or a total for Great Britain of 11,694,792 acres. Then there are 12,788,165 acres of mountain and heath land used for grazing, or altogether 24,482,957 acres. There are of course difficulties in the way of making land available, even land that is now used for so-called light grazing, but these difficulties ought not to be insurmountable. It is impossible to say what portion of this waste and heather is available for proper afforestation but it must be considerable. It would not be easy to deal with the rights of grazing, and in some districts they would prevent afforestation, but in many cases the difficulties might be overcome.

The Preference for Foreign Timber.—However regrettable, the preference for foreign timber is easily understood. It is not to be attributed to unsuitability of soil or climate, but is entirely due to neglect of agricultural principles. Timber of the kind and quality imported in such large quantities from the Baltic, and elsewhere, can be grown as well here as anywhere, in fact, Continental "red wood" and "white wood," so highly esteemed for structural purposes, are yielded by the Scots pine and the spruce, two of the commonest trees of British woodlands. But until recent years, owners of woodlands failed to realise that the shape, size, and quality of trees could be influenced by anything they could do. They seemed to imagine that the character of the final product was largely a matter of accident, whereas it is mainly determined by management. They failed to realise that cultural treatment which suits oak or ash, is unsuited to pine or spruce, and this explains why British coniferous timber has been generally excluded

from building specifications. Indeed few landowners took any personal interest in their plantations. Here and there more enlightened management might be found, as on the Duke of Bedford's estates, but the exceptions were few. For, speaking generally, the landowner does not make up for his own indifference by employing competent, and therefore well paid foresters, as in Germany. There are still estates in Scotland with 20,000 acres of wood without an efficient forester, managed by men getting 30s., or even less, a week.

Afforestation and Labour.—It may be urged that it is not desirable to turn cultivatable land into woodlands, since labour would be displaced, but in fact land under forests would give healthy employment to a much greater number of persons than the same area under sheep. "Many hill pastoral farms," the Committee say, in their report, "have one shepherd to three or four thousand acres, but much of such land, for various reasons, is unsuited to the growth of timber for profit. We believe that we are within the mark in assuming that land capable of producing high-class timber employs only one shepherd per 1,000 acres if used as a sheep run, while all the evidence on this point goes to show that similar land when under timber gives employment to at least one man per 100 acres, and this without taking account of the labour requisite to remove and work up the timber." The Committee pointed out the importance of afforestation in such a district as the Highlands of Scotland. Rough land is extensive, capital as a rule scarce, and great woodland areas, where well managed, have proved financially successful, while profits on sheep farming have of late years reached a very low point. Almost nine-tenths in value, and over nine-tenths in quantity of our present imports of wood consist of pine and fir timber capable of being grown at home, and nearly three-fourths of this coniferous wood in quantity, and more than four-fifths in value, are imported as sawn or split. If we could grow our own supplies of wood, large sums now spent abroad would be distributed among the industrial classes at home in addition to the large labour bills that would be payable in the woodlands themselves.

The World's Supply of Timber.—Unless the Canadian forests are treated more scientifically—very large tracts have already been destroyed by indiscriminate clearance, forest fires, and otherwise—it is not unlikely that there will be a shortage of timber before long. The only sources of a large supply of conifers are the countries round the Baltic and North America. A little comes from Australia—£163,411 worth of wood and timber in 1904—a little less from the Gold Coast, and small quantities from other colonies. There are extensive forests in the back part of the Argentine Republic, but at present the difficulty of getting out the timber is very great. There are believed to be great forests in the western part of China round about the broad waters of the big rivers, but as soon as the trade and industries of China have developed—and they are developing rapidly—the home market will want it all, and more. So that for the most part we have to rely upon the Baltic and North America. As to Russia, only about 25 per cent. of the country has more forests than are required for home consumption—the quantity of timber required for local needs where, as in Siberia, most of the houses are built of wood and burnt down once in every twenty years or so, where the long winters demand an immense consumption of fuel, and the railway, steamers, and all the new industries depend largely on wood both for construction and for fuel, is necessarily very great. The supply from Sweden and Norway is much less than it was, and although there is an immense area of forest land in Canada, of which more than a fourth may be classed as timber forests, the exports to the United Kingdom do not increase. Indeed the value of all kinds of timber received by Great Britain from Canada in 1904 was only £12,618,267, as compared with £13,878,839 in 1903. The supply of hard woods is ample, reference here is limited to coniferous timber.

The Obstacles to Afforestation.—Much as the extension of afforestation is to be desired on national grounds, it is to be feared that landowners will not extend the forest area to any great extent unless they are encouraged to do so by some alteration in their favour in the incidence of rates on plantations. Rates and taxes together sometimes amount to 7s. or 8s. an acre, and it has been suggested that landowners who are prepared to lay out some money on plantations should be relieved of rates altogether for a period until some income is derived from the woodlands. The Forestry Committee did not see their way to make this recommendation, nor were they willing to recommend that the State should advance loans to encourage afforestation. The many years the landowner has to wait for a first return is perhaps the chief obstacle to afforestation. He does not care to submit to a present sacrifice in order to secure an ultimate return that may benefit his successor rather than himself. Eight shillings per acre per annum for rates and taxes, plus the cost of looking after the plantations, with absolutely nothing coming in, does not commend itself to men many of whom, with falling rents and fixed charges, find it difficult to pay their way. And it must be borne in mind that planting is very expensive work. The cost of making plantations is far greater than it used to be. From 30s. to £2 an acre it has grown to from £6 to £8; the cost of plants and labour is twice as great as formerly, and the swarms of rabbits necessitates wire netting costing from 50s. to £3 per acre planted. Moreover, many landowners under-rate the value of woodlands, and what they can be made in time to return under scientific management. Here the State might do

much by the provision of adequate facilities for instruction in afforestation. And it is satisfactory to know that some steps are being taken in this direction. But a large area of woodland for purposes of practical demonstration is a necessity.

OBITUARY.

CHARLES WENTWORTH WASS.—By the death of Mr. C. Wentworth Wass, the Society loses one of its very oldest members, his election dating as far back as 1849. Mr. Wass was born in London, 1817, and was intended for the Church. But at the age of 16 he was apprenticed to the engraver, Richard Woodman, and during the period of his apprenticeship, in 1835, he obtained the Silver Isis Medal of the Society for a copy in chalk of a historical subject. At the end of his apprenticeship, he took chambers in the Adelphi, and started as an engraver. Amongst the works produced by him were engravings of works by Etty, Landseer, Ansdell, Poole, Bateman, Herring, and Sant. Much of his work was produced by a combination of etching, mezzotint, stipple, and line, and he was one of the most successful workers by these mixed methods. When the Crystal Palace Picture Gallery was established, Mr. Wass was appointed its superintendent, a post which he held until about five years ago when the directors of the Palace decided to give up the Gallery. Mr. Wass was considered an excellent judge of pictures and of china, and during his long life he accumulated a collection of works of art, believed to be of considerable value.

GENERAL NOTES.

EDUCATION OF APPRENTICES.—The Board of Education have issued a memorandum on the subject of co-operation between employers of labour and school managers with regard to the instruction of *employés* or apprentices. The Board desire to secure the assistance and co-operation of employers in encouraging the education of their apprentices, and they take note of several ways in which such assistance can be rendered. These are summarised as follows:— (1) Paying the fees for *employés*, or offering prizes to those who pass the examinations of the Board of Education, of the City Guilds' Institute, or the Society of Arts. (2) Increasing the wages of apprentices who have passed through an approved course of study, who attend regularly at approved evening classes, or who have passed approved examinations. Or instead of an actual increase in wages, increased efficiency may be recognised by promotion, or by transference from an inferior to a superior department. (3) Making concessions in the matter of working hours, so as to allow all *employés* the opportunity of attending classes. (4) Providing scholarships, or maintenance and fees, for a few selected and specially qualified students. (5) Taking part in the organisation of technical institutes or schools, and helping such establishments by personal supervision and interest.

TRUSTEE SAVINGS BANKS.—The report of the proceedings of the Inspection Committee of Trustee Savings Banks recently issued, shows that the period of twelve months covered by the report—November, 1903-1904—was not a prosperous one for Trustee Savings Banks, as although there was a slight increase of £170,000 in the Government Stock held on behalf of depositors in Trustee Savings Banks at the end of it, there was, on the other hand, a decrease of about £260,000 in the cash due to depositors, as apart from special investors. The explanation is not far to seek. In several towns, the local authorities are accepting small sums for deposit, offering a charge upon the local rates as security, at rates of interest which look very inviting compared with the 2½ per cent. to which Trustee Savings Banks are restricted by law. One county borough accepts deposits, as low as £10, at 3 per cent. interest. This tends to intercept the flow of small savings to the Trustee Savings Banks, and even to draw money away already deposited. Then certain joint stock banks are opening savings banks departments for the issue of deposit books, accepting for deposit sums of one shilling and upwards. "These competing agencies," says the report, "may have an important effect upon Trustee Savings Banks, whose hold, nevertheless, upon the industrial classes is a strong one, and the trust and confidence which is the growth now of close upon a century is not likely to be greatly weakened, provided the management keeps pace with the times, and trustees and managers can be found able and willing to continue their gratuitous services."

THE AREA UNDER WHEAT.—The anticipation that the area under wheat in Great Britain would show an increase in 1905 as compared with 1904, is confirmed by the preliminary statement for 1905, compiled from the returns collected on June 5th, and issued by the Board of Agriculture. The total acreage under wheat in 1905 is put at 1,796,985, as compared with 1,375,284 acres in 1904, an increase of no less than 421,701 acres, or 30·7 per cent. The acreage under wheat for the current year is higher than for any year since 1900, when it was 1,845,042. No doubt the rise in price has been the main cause of the increased acreage of the present year. The average price of wheat in 1904 was 28s. 9d. per imperial quarter, a higher average than in any year since 1898, when it was 34s. It is noteworthy that the present year's acreage of barley and oats shows decrease, the one of 6·9 per cent., the other of 6·2 per cent., as compared with 1904, and barley at the average price of 22s. 4d. per quarter, and oats at 16s. 4d. per quarter, were lower in 1904 than in any year since 1895 in the case of barley, and 1897 in that of oats.

Journal of the Society of Arts.

No. 2,759. VOL. LIII.

FRIDAY, OCTOBER 6, 1905.

NOTICES.

PRIZES FOR INDUSTRIAL DESIGN.

The Council of the Society of Arts hold a sum of £400, the balance of the subscriptions to the Owen Jones Memorial Fund, presented to them by the Memorial Committee, on condition of their spending the interest thereof in prizes to "Students of the Schools of Art who, in annual competition, produce the best designs for Household Furniture, Carpets, Wall-papers, and Hangings, Damasks, Chintzes, &c., regulated by the principals laid down by Owen Jones."

The prizes will be awarded on the results of the annual competition of the Board of Education, South Kensington. Competing designs must be marked "In competition for the Owen Jones Prizes."

No candidate who has gained one of the above prizes can again take part in the competition.

The next award will be made in 1906, when six prizes are offered for competition, each prize to consist of a bound copy of Owen Jones's "Principles of Design," and the Society's Bronze Medal.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

TELEPHONY.

By Herbert Laws Webb.

Lecture IV.—Delivered April 3rd, 1905.

Tariffs and Development.

The table shewing the comparison between a message and reply transmitted by telegraph and a message and reply transmitted by telephone (p. 1092), illustrates very pointedly the reason for the supremacy of telephonic communication. It is seen that work which takes an average of an hour and a-half, and requires for its completion numerous transactions on the part of a whole train of individuals and machinery, is done even more effectively by telephone in about a thirtieth part of the time. It is clear that for speed, directness and completeness, since the message and reply are handled in the one operation, the telephone service very greatly out-distances the telegraph service, which was the most rapid means of communication previous to the organisation of the telephone service. In addition to the great advantages of speed and completeness, the telephone service has the further advantage of being much cheaper than the telegraph. The minimum cost of a message and reply by telegraph is one shilling, and the average cost is slightly higher. The average cost to a telephone subscriber in this country of a message and reply is under 1d. for the local service, and the Post Office report shows that the average cost of a trunk telephone call is less than 6d. For local communication, therefore, the telephone service is cheaper than any other means of communication, cheaper even than the half-penny post-card.

In the long-distance, or trunk service, the charges as the distance increases are greater than the minimum charge for a telegram. But the trunk telephone service is really cheaper than the telegraph for the great majority of transactions, by reason of its greater carrying capacity. In a three minutes conversation by telephone, more matter can be transmitted or exchanged than could be transmitted or exchanged by telegraph for the same price. Comparisons of long-distance telephone rates with telegraph rates generally ignore this point, and contrast the rate for a three-minute conversation, which may contain 300 words, with the rate for a ten or twelve word telegram. Even where long-distance telephone rates really mount into large sums on account of the very long distances covered, as, for instance,

between New York and Chicago, where the rate is about 20s. for three minutes conversation, business people willingly pay the charge, because the service rendered is so great. In the longer distances, the telephone competes more with the railway than with the telegraph, as business men get direct interviews with each other, and so save the time and expense of the journey which would otherwise become necessary. It has been found since the long-distance telephone service has become a familiar part of business machinery, that many transactions which could not be completed by telegraph, but would necessitate a personal distance telephone service, in spite of its apparently high cost, is really a most economical method as a saver both of money and of valuable time.

For local communication in large cities, the telephone service is absolutely supreme, both on the score of rapidity and of cheapness. With whatever means of communication the comparison be made it is found that the telephone message, even when made at the highest price from a public station, is cheaper than the message transmitted by other means, and if all the various items of cost are taken into account it is cheaper than the average business letter.

TABLE I.—Comparison of Message and Reply by Telegraph and Telephone.

Telegraph.			Telephone.		
Steps.		Minutes.	Steps.		Seconds.
1	Writes message	2	1	Calls exchange	2
2	To telegraph office	5	2	Operator answers	5
3	Checking, affixing stamps	1	3	Receives number	3
4	Message to operator	1	4	Operator passes call to operator at distant exchange	8
5	Transmission (including time message is waiting its turn)	20	5	Distant operator connects and rings	5
6	Checking and addressing	1	6	Called subscriber answers	10
7	Delivery by messenger	10	7	Conversation: — Message and reply	120
8	Receipt of message	1	8	Disconnection signal	2
9	Writes reply	5	9	Lines disconnected	5
10	To telegraph office	5		Total seconds	160
11	Checking and affixing stamps	1		2 minutes 40 seconds.	
12	Message to operator	1			
13	Transmission (same as No. 5)	20			
14	Checking and addressing	1			
15	Delivery by messenger	10			
16	Receipt and reading	1			
	Total minutes	85			
	1 hour 25 minutes.				

interview, can be satisfactorily completed by telephone—which provides a personal interview, and saves the journey. To take New York and Chicago, as an example, the round trip from one city to the other and back, allowing a day for the interview, occupies practically three days' time and costs in expenses, approximately £15. The business man who can effect his object by using the telephone for fifteen minutes at the cost of £5, or even for half-an-hour at a cost of £10, willingly does so in order to save the three days' time, to say nothing of some saving in expenses. Even in distances of considerably less than a thousand miles, the same principle holds good—that the long-distance telephone service ... The high efficiency of the local telephone service, its great rapidity, the directness of the personal interview which it affords, and the completeness of the transaction, which embraces message and reply, or comment, in the one operation, and the extreme cheapness of the service, are the underlying reasons for the great development of the telephone service in all large cities where the service is effectively managed.

Requirements of the Telephone Service in Large Cities.

To give the telephone service its true value in large cities, the service must be highly efficient

and must be widely developed. The remarks above refer to the relative efficiency of the telephone in comparison with other means of communication. The efficiency proper of the telephone service means a rapid, accurate, and reliable service. It is essential that a city telephone service shall be reliable, that is, free from interruptions. One must always be able to count on the service being available at any moment of the day or night. Such a service, absolutely reliable and uniformly accurate and speedy, can only be provided by the methods which have been described in the previous lectures, namely, standard common battery switchboard and subscribers' station equipment, and a complete system of cable distribution. With such a plant, operated by a well-organised and well-trained staff, the delays, inaccuracies, and interruptions which in former years largely marred the efficiency of the telephone service almost wholly disappear. The design and construction of such a plant, involving the proper selection of sites for telephone buildings, the construction of adequate and suitable buildings and exchanges and of a distribution plant suitable to the area to be served, are matters calling for a high degree of engineering skill; and the maintenance of such a system, and the proper handling of the enormous volume of traffic which flows daily over a modern city telephone system, require the highest skill in organisation and management. But the science of telephony has progressed so far, both on the technical and on the commercial sides, that there is to-day no real difficulty in providing any city with a thoroughly efficient telephone service, capable of extension to almost indefinite limits.

In this country the ideal standard of telephone service has not yet been reached, though steady progress is being made in placing the telephone service of British cities on modern lines. It would hardly be appropriate in these lectures to enter deeply into the causes which have prevented the progress from being made in Great Britain with the telephone that has been made in the United States. The great difference may be attributed, broadly speaking, to the difference in conditions. In America, telephony is a free business; in this country it has been, from its earliest days, a Government monopoly, subject to the frequent changes of policy which occur under Government control, and for these reasons it has been impossible to develop the business on the broad lines which have been followed in America, where no question of Government monopoly or Government control exists to interfere with the normal development of the industry along business-like lines.

However, whether management of the telephone business be departmental or commercial, the real requirements and conditions of the business remain the same. In a large city, the standard of telephone equipment and service to-day is what has been described, and anything else is inadmissible. It is far more important to the community at large to have a highly efficient service and a widely developed service, one which can absolutely be depended on for speed and reliable working, and one which reaches the widest possible number of users, than to have a very cheap rate for any one particular class of service.

TELEPHONE RATES.

Telephone rates form a very controversial and complicated subject. The principal difficulty is that from the very beginning of the business the wrong unit has generally been adopted. The vast majority of people regard the telephone instrument as the unit of the business instead of the telephone message, which is the true unit. The general adoption of the "flat rate," or fixed annual charge for unlimited service, has been the cause of almost all the misunderstanding and controversy in connection with the vexed question of telephone rates. The adoption of the flat rate came about in a natural way, as the earliest telephone exchanges were combinations of owners of private telephone lines. The earliest use of the telephone was on private lines, and the next step was for a number of owners of private lines to combine their lines into an exchange, forming a sort of telephone club, each member of which paid an annual subscription for maintenance and service. In this way the flat rate became the accepted thing and the telephone became the accepted unit of the business. In very small places, where the average amount of plant in use for each subscriber is a fairly equal quantity, and the average amount of service rendered to each subscriber is also a fairly equal quantity, the flat rate is quite a suitable arrangement, but in large cities the conditions differ very greatly from those which obtain in small places. The amount of plant used by each subscriber varies greatly, and the amount of service rendered to each subscriber varies still more widely. The subscriber's telephone instrument is really only a means for using the service, and in no

way represents the amount of plant used by the subscriber or the amount of service rendered to the subscriber. To maintain flat rates in large cities is, therefore, to ignore the actual conditions under which the business is carried on.

The general adoption of the flat rate has been a fundamental error, and around this error there has arisen a long-drawn-out controversy which is frequently rendered still more obscure by the superficial and misleading comparisons which are so often made between rates in different countries and different cities. These comparisons are almost always misleading, since they do not take into account the wide and numerous differences in general conditions which exist, and very generally they are also inaccurate, comparing, for example, a rate for one class of service in one place with a rate for another class of service in another place. Comparisons of telephone rates in different countries are of little value unless all the details are known and all surrounding conditions are taken into account and fairly compared. The differences in conditions are generally so great and so numerous that it is a very difficult matter to establish comparisons that are of any real practical value. It is the experience of those who have given the most study to the subject that the only just method of judging telephone rates is in accordance with the actual conditions which obtain in the particular place where the service is furnished.

Although the flat rate is almost universally quoted in discussions of rates for telephone service, and most people speak of hiring or renting a telephone, yet there is a great variety in the methods of charging for telephone service in different places. In some places the subscriber pays an installation charge in addition to the annual rate. In others he pays the cost of building his line and then pays an annual rate. In others he has to buy his own instruments and pays an annual rate for the use of the line and for the service. In others he has to provide the instruments and to pay part of the cost of establishing the line. In all these cases the annual rate may be increased by mileage charges if the subscriber is more than a certain distance from the central office. The rate is sometimes higher for business service than for residential service, and in some places the rate increases as the number of subscribers in the system increases. In all countries it is the practice to charge higher rates in the large cities than in the smaller towns.

Then there is also a variety of schemes of message rates. The general principle of the message rate is that each subscriber pays in proportion to his individual use of the service, and undoubtedly this is the correct principle. There are two general methods of message rate; one in which the subscriber pays a fixed annual rate for the line and station plus a charge for each call originated, the other in which he pays a minimum rate for a certain minimum number of messages, the rate then rising in accordance with the annual number of messages used. A feature of this system is that the price per message diminishes as the number of messages used in a year increases. So far it has not been found practicable to charge a message rate pure and simple, *i.e.*, to install lines and telephones with no guarantee of use. Where this experiment has been tried it has been found in many cases that the use of the service by some customers has been so small as to make those customers unprofitable. No doubt in time the use of the telephone service will be so general, and the telephone plant in large cities will be so extensive, that it will become the practice to lay on the telephone service at any address without a guarantee of use, the customer to be charged simply for the messages which he originates. At present, however, we have not reached that stage in the development of the service.

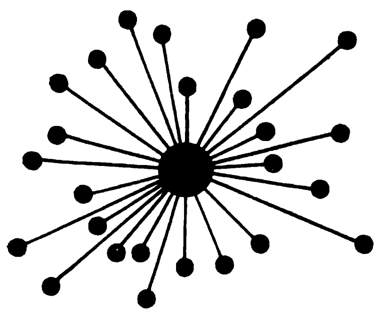
Several other varieties of telephone rates also exist in actual practice. In some cases it is the practice to make the subscriber pay the whole cost of establishing his line, and then to pay an annual charge for maintenance and a charge for service, the service charge varying in accordance with the number of subscribers available. A similar method obtains in some of the small co-operative companies which work in the rural parts of America and in the Scandinavian countries. Some of these systems are very cheaply constructed, usually with iron wire and often with second-hand instruments, and, as the subscribers very often do a large part of the work of construction themselves, and even keep their own lines in repair, a very small service charge for the upkeep of the exchange is required from each subscriber, and a very economical service results. Sometimes rates which obtain in this class of co-operative telephone system are quoted in comparison with rates for city telephone services operated

under entirely different conditions, and it may readily be seen that such comparisons can be of no practical value.

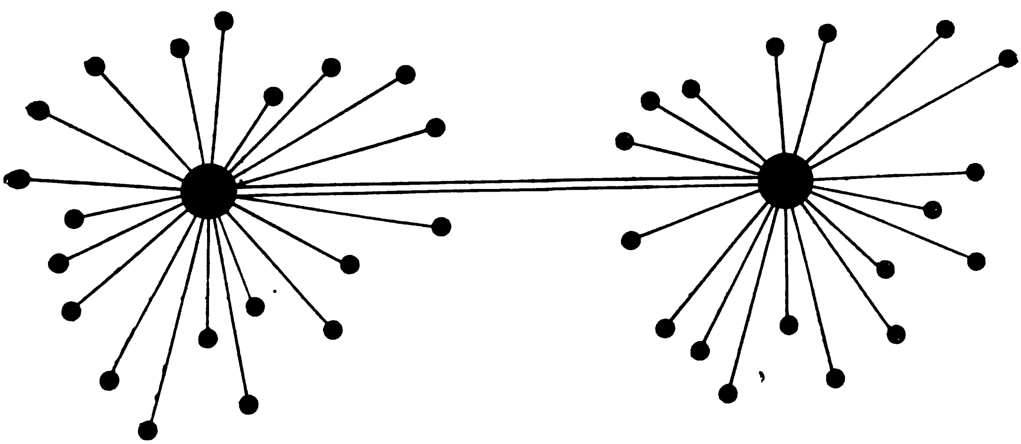
In general the principle that the message is the true unit of the telephone service is now fairly recognised, and the further important principle that the value of the message exchange, in which case the switchboard equipment is comparatively simple, and the length of travel of the message is limited by the combined lengths of the two longest lines in the system. When the size of the area is increased it becomes uneconomical to serve the whole area from a single exchange; then

FIG. 32.

SINGLE EXCHANGE AREA.



DOUBLE EXCHANGE AREA.



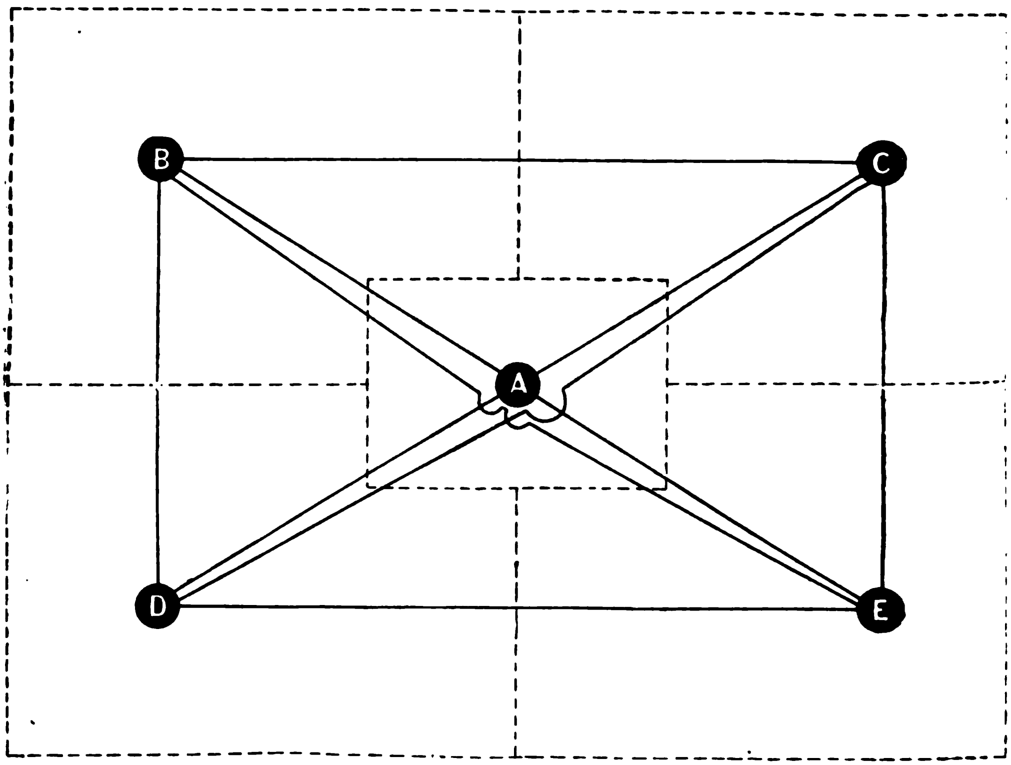
depends upon the size of the area served, which governs the actual distance travelled by the average message, is also becoming recognised.

The diagrams, Figs. 32 and 33, illustrate roughly the difference in the plant requirements of different sized areas. A very small area may be adequately served by a single two or more exchanges are installed, and the exchanges are interconnected by junction lines. This involves greater complication in the exchange equipment, as special equipment must be provided for operating the junction lines both at the outgoing and at the incoming ends, and it involves a greater amount of line plant per subscriber, as the

junction lines are additional to the subscribers' line plant. As the size of the area increases more exchanges have to be employed, the area being split up into districts, each district served by its corresponding exchange, and all of these exchanges must be interconnected by means of a comprehensive system of junction lines. The exchange plant of the large city system is very greatly complicated by the fact that by far the larger proportion of the traffic has to be passed over the junction line plant. The amount of equipment at each exchange which is required exclusively for the operation of the junction lines is a very large proportion of the whole exchange equipment, and this results in the city telephone exchange being of an entirely different character from the exchange which provides a purely local service. The actual amount of junction line plant in a large city telephone system is also a considerable proportion of the total line plant required, and this may readily be imagined when it is considered that in a large city in the case of three calls out of four the subscriber's demand is that his line shall be extended a distance which may range anywhere from one mile up to, in the case of London, 25 or 30 miles, in order to reach another subscriber's line in another part of the area. The diagram illustrating the plant conditions of a multiple exchange area gives but a feeble idea of the conditions of a large city telephone plant, in which there are many exchanges, every two of which must be directly connected by a complete junction line system. London affords the most unique example of the extensive and complicated plant required to cope with the telephone service of a large city. The London telephone district covers an area of 640 square miles, and within that area there are telephone exchanges distant 30 miles apart in a straight line. It is clear from these conditions that the telephone message must necessarily have different values in different places, since the range of travel of the message differs so widely.

FIG. 33.

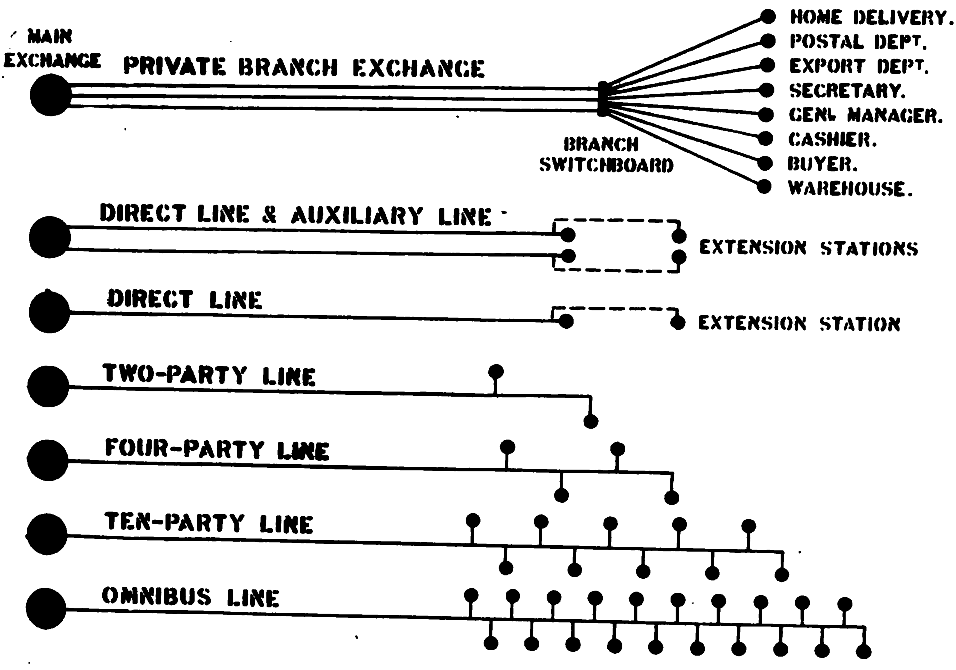
MULTIPLE EXCHANGE AREA.



The diagram, Fig. 34, illustrates the different classes of telephone service which are supplied to the modern telephone user. The variety of classes of service which may be supplied to the public illustrates again the uselessness of comparing telephone rates by the process of picking out one particular rate for purposes of comparison. As a matter of fact, the demands of different customers vary very widely, and in order to meet these varying demands, and to produce a comprehensive tariff which shall meet the requirements of all possible customers as regards price, as well as to suit the requirements of different customers as regards quantity and quality of service, the methods of supplying telephone service to the consumers have been largely modified. In the early days, the direct telephone line was the only class of line supplied to the public. As it was found that the line plant represented the largest part of the cost of establishing and maintaining a telephone service, the device of supplying two or more subscribers by means of one line was adopted as a logical method of arriving at a reduced rate for each of the several subscribers so supplied. This "party-line" service has been very largely extended in response to the demand for cheap rates, and whereas at first party lines were usually limited to two subscribers it is now the practice to supply as many as twenty small users by means of one main line, and in some of the rural districts of America an even larger number of stations is served by one line. On the other hand, some subscribers use the service very largely, and a single direct line is not adequate to supply their needs. The simplest means of relief for an over-worked line is to supply an auxiliary line, and to work the two on a double-track arrangement, using one line for outward messages and the other for inward messages. But there are many large businesses and large establishments which have so great a demand for the telephone service that no arrangement of direct lines, each attached to individual instruments, will fulfil the requirements. For such establishments the "private branch exchange" has been devised. This arrangement consists of a switchboard on the subscriber's premises connected to the nearest main telephone exchange by a group of two, three, or more junction lines,

FIG. 34.

DIFFERENT GRADES OF TELEPHONE SERVICE.



and connected to all the different departments in the subscriber's establishment which require to use the telephone service by extension lines and instruments. In this way an unlimited number of points in the one establishment can be directly supplied with the telephone service, and an unlimited amount of daily traffic can be handled expeditiously and satisfactorily. The flexibility of the system is obvious; the equipment can be increased or diminished according to the requirements of the traffic. The private branch exchange switchboard, served by one or more operators, acts as a distributor of the traffic, directing all inward traffic to the instrument of the particular individual wanted, and, in conjunction with the operators at the main exchange, directing all the outward traffic to its proper destination. The private branch exchange has very largely aided in placing the telephone service of large cities on a businesslike and thoroughly useful basis. This class of service is now a regular part of the equipment of all large business establishments and of large hotels and apartment houses or flat dwellings in American cities.

From the above discussion of the theory and practice of telephone rates, of the variation between the telephone plant of small places and large places, and of the variation between the demands of different individual consumers, it will be seen that there are three broad considerations which should govern telephone tariffs, apart altogether from the local conditions, which must be studied in order to arrive at the actual prices to be charged. These three broad conditions are:—the size of the area to be served, the amount of service supplied to each individual, and the class of equipment supplied to each individual.

It is clear that the size of the area must exercise a governing influence on the rates to be charged, since the size of the area governs the average distance the message has to be carried. That the rates should vary with the individual use of the consumer is such a commonsense principle that few will be disposed to quarrel with it. Finally, since different consumers can be supplied by different classes of equipment, one consumer requiring the most perfect arrangements possible while another is content with arrangements which are relatively inferior but fulfil his requirements, it is only practical business management to supply the service with such modifications in equipment as enable modifications of rate to be made to suit different purses.

Telephone Development in Different Countries.

The following tables (Tables II. and III.) show the relative development in the use of the telephone in the principal countries and in the chief cities or capitals of those countries. The relative telephone development in the

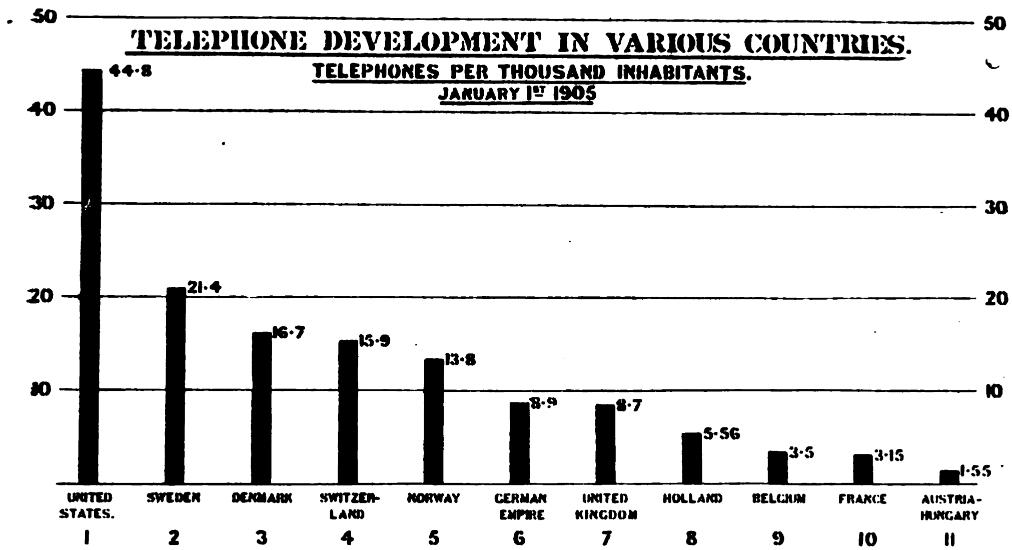
Lisbon	370,000	1,740	212	·47

different countries and cities is also shown diagramatically in Figs. 35 and 36. It will be seen from these tables and diagrams that except in America there is no really high development of the use of the telephone. In Europe, speaking generally, the development of the telephone has been artificially restricted by the existence in almost all countries of a Government monopoly in telegraphy which has unfortunately been held to include the telephone. This has brought the whole telephone business under political control, and such control notoriously does not make either for commercial or for technical progress.

phone service has entered into the general life of the people to an extent that is not approached in any European country.

That under similar conditions similar results might have been reached in this country there is very little reason to doubt. With the same business-like policy of expansion and with the same enterprise in developing the service to the full extent of the public demand and even of educating the public up to the demand, as is practised in America, a very similar rate of development could be obtained in Great Britain. Such a policy has not been practicable here owing to

Fig. 35.



It is interesting to observe that the largest relative development of the telephone in Europe has been in the Scandinavian countries, and the relatively high rate of progress in these countries has been due to the fact that a strict Government monopoly in telegraphy either did not exist or has been exercised with less restrictive effect than in other countries.

In America the telephone has been entirely free from official control or interference, as there has never been a Government monopoly in telegraphy in the United States, and there has been no attempt on the part of the Federal Government to establish such a monopoly or in any way to impose restrictive regulations on either the telegraph or the telephone business. As a result the use of the telephone has been developed in a thoroughly business-like manner, and the employment of the tele-

the numerous restrictions arising from the Government monopoly. The relatively large development in the Scandinavian countries is an illustration of what can be done even in relatively poor and sparsely populated counties if private enterprise is allowed a fairly free hand. The large use of the telephone in Stockholm, which is frequently quoted in this country, is due to somewhat special circumstances, as for many years there has been an active competition in the telephone business in Stockholm between the State Telegraph Department and the Stockholm General Telephone Company. This has resulted in extensively advertising the telephone business in Stockholm, as each party to the competition maintains strenuous endeavours to secure new subscribers. The Company system is much the larger of the two, and continues to in-

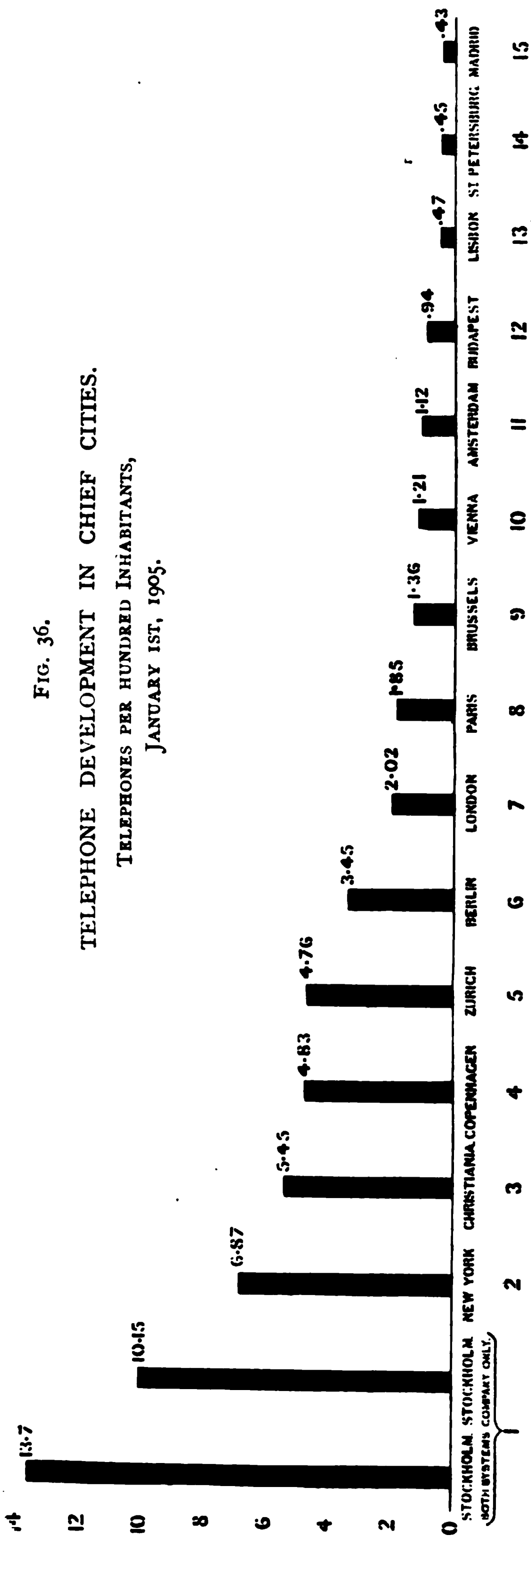


Fig. 36.

TELEPHONE DEVELOPMENT IN CHIEF CITIES.

Telephones per hundred Inhabitants, January 1st, 1905.

crease more rapidly, while a very large proportion of the subscribers to the State system are also subscribers to the Company system, thus involving the duplication of plant and subscriptions which is a familiar feature of all cases of telephone competition.

To achieve a sound and efficient development of the telephone service, there are several essential requisites peculiar to the telephone business which are little understood in European telephone administrations owing to the unfortunate fact that political control, too prone to take matters for granted, has discouraged in Europe the study of telephony as a specialty. Properly to develop the telephone service of a large city, with due regard to economy and efficiency, needs high engineering skill to lay out a very complex and costly plant in accordance with the requirements of the population, and on such lines that it may be developed economically with the growth of the population. To secure efficient maintenance of the whole system of delicate switchboard apparatus and numberless ramifications of wire plant, and to maintain a reliable and efficient service, needs expert supervision of a high order and a highly-trained staff especially adapted to the work. To exploit the service as a business, and to educate the public to its value and how to get the best results from it in actual use, needs a business management and organisation of a very high order. It is, unfortunately, the fact that these essential characteristics—which almost amount to laws—of telephony as a business have been very largely ignored and neglected by European telephone administration.

One great difficulty connected with the development of a large telephone system is that it must be conducted with an eye to the future. To develop scientifically and economically needs a very careful study of the distribution of the population and of its probable future distribution, of the growth of the population, of the number and distribution of the probable future subscribers, and of the volume and probable distribution of the future traffic. Without a very careful study of the probable future conditions along these lines the development of the plant cannot be undertaken either effectively or economically. If no such study be made the result assuredly will be waste and inefficiency.

Owing to the lack of scientific study of the conditions of future development, there is hardly a city telephone system in Europe today which is capable of taking care of the

actual business which offers, and there is not one, unless it has been completely rebuilt during the past few years, which is capable of indefinite development along economical lines.

A very important feature of the city telephone system is that it must contain a large margin of spare capacity, not only because there is constant growth going on which must be provided for, but also because there is constant change in the telephonic population, to cope with which requires a flexibility in the plant, which can only be obtained by having a margin of spare facilities in all directions. It is not uncommon, owing to old subscribers going off and new ones coming on in different places, owing to removals and to changes in the amount of telephonic equipment required by different subscribers, for a telephone system to be required to make three changes in the plant for every single new station gained. As an example of this, in one city there were in a period of less than a year 12,981 new stations put in and 7,456 stations taken out, making a total of 20,437 changes in the plant for a net increase of 5,525 stations. Figures on a similar scale would be obtained from any large and progressive telephone system. Unless there is a large margin of spare facilities, so that the new subscriber can be taken on wherever he offers and the line of the discontinuing subscriber held vacant until another customer appears, and so that the service can be changed from one address to another without difficulty, the public is not properly served and the service is not an efficient one in the full sense of the word. Therefore, these spare facilities are required not alone for future development, but to carry on effectively the business from day to day. In various city telephone systems in different parts of the world the provision for the future is so small that not only is the development of the service practically arrested, but proper facilities cannot be given for the changes that are daily required to meet the varying demands of different subscribers. In some places it is not uncommon for the line of a subscriber who for some reason wishes to give up the service to command a high premium, so great is the demand for the service among business people and so restricted the facilities for supplying it. In some places there are actually more applications on file for the service than there are subscribers connected. These are extreme examples of what occurs when a business is operated under artificial conditions.

That the direct usefulness of the telephone service to a very large proportion of the public and its indirect value to the community at large entitle the telephone to much more intelligent and enlightened treatment than it at present receives in most European countries has perhaps been partly demonstrated by these lectures.

In the course of the lecture several slides were shown in which the area of London was contrasted with the area of other great cities. It would hardly be useful to reproduce these slides, but they showed that no other of the world's great cities approaches London in the size of its area. The area of Paris is 31 square miles, or about ·05 of London. Berlin is 28 square miles, Vienna 21, St. Petersburg 20, and Manhattan and the Bronx, or old New York, 62 square miles. Greater New York, which comprises Brooklyn and Staten Island, and is served by three separate telephone systems, all intercommunicating however, covers a total area of 307 square miles, or a little less than half the London telephone area.

Most hearty thanks are due for the loan of apparatus, lantern slides, and for other facilities, to Mr. John Gavey, C.B., Engineer-in-Chief, G.P.O., to the National Telephone Company, the General Electric Company, and the Western Electric Company, and to the British Mutoscope and Biograph Company for the interesting moving pictures of a telephone exchange, made by permission of the National Telephone Company, which were used to illustrate the third lecture.

GRADUATED INCOME TAXES.

At the instance of the Treasury, His Majesty's representatives abroad have compiled a series of reports respecting graduated income taxes in foreign States. These reports have just been published (Cd. 2587), and they are prefaced by an interesting report by Mr. Bernard Mallet, Commissioner of Inland Revenue, who has classified and summarised the information received. Before referring to the very various systems adopted by foreign States it may be convenient to mention the States which dispense with an income tax. In France there is at present no graduated income tax, or indeed any impost in the nature of an income tax except the "contribution personelle mobilière,", the doors and windows tax, and the tax of 4 per cent. on incomes derived from all kinds of securities, such as shares of companies or debentures, excepting interest on State funds, French and foreign. In Russia there is no income tax proper. In Portugal no attempt is made to tax the income of the taxpayer as such. No income tax proper can be said to exist in Belgium, the only State tax in any way resembling an income tax being that of 2 per cent. levied on the dividends of joint stock companies. In Hungary there is no tax,

whether graduated or not, corresponding to a general income tax such as in force in England. In the United States no income tax is levied. A statute was enacted by Congress in 1894 providing for a general tax on incomes derived from all sources, but by decision of the Supreme Court, in the case of "Pollock *v.* Farmers Loan and Trust Company," such a Federal tax was declared to be unconstitutional. Nor is any income tax levied in any of the States of the Union, with the exception of North Carolina, where a tax of 2 per cent. is payable on income derived from all sources in excess of 1,000 dols.

In States where an income tax is levied it differs widely in general character. In no two countries is it identical or near it. Some of them are taxes affecting the whole income of the taxpayer, such as the Prussian income tax, while others are designed either to supplement existing taxes, or to fall only on certain sources of income which are not reached by such taxes. In no foreign State is the maximum of exemption anything like so high as in the United Kingdom; in all foreign States there is graduation, and in most differentiation. As to graduation, the principle adopted may be the exemption or partial exemption of the smaller incomes, or of certain classes of income tax payers, or by some more regular system of progressive taxation, or by both methods. Differentiation taxes "unearned" income, that is to say income from property or investments, at a higher rate than income from personal labour, and this may be effected in various ways; for example, either by taxing different kinds of income at different rates, or by a combination of a tax on realised property with a tax on income proper. The income taxes described in the Reports are all State taxes as opposed to taxes levied for local purposes. Two main groups, the German and Swiss taxes, are imposed by States belonging to a confederation, but these taxes all form State and not local revenue. In neither of these cases does the Federal Government at present levy an income tax.

The exemption of a certain minimum income is a principle recognised in one shape or another in all the States reported upon, but the limit of exemption differs widely. It is highest in Holland at £54, lowest in Norway at £18. In Austria it is £50. In Prussia and Bavaria it is £45; in Denmark, according to locality, £33, £39, and £44; in Spain, for private individuals, £45, and for State *employés*, £31. In Italy, differentiation takes its most elaborate form. By it incomes are classified according to their character, and "discrimination" is applied by which the net or taxable income is reduced in the following proportion:—(1) Incomes are assessed at their integral value, and pay the full tax of 20 per cent. This class comprises interests on capital, and perpetual revenues, owed by the State (*i.e.*, mortgages, ground rents, fixed annuities, &c.), interests and premiums on communal and provincial loans, dividends of shares issued by companies guaranteed or subsidised by the State lottery prizes. The rate in this category is 20 per cent. (2) Here the income assessed is reduced to 30-40ths of the actual income in this class, which consists of all incomes derived from capital alone, and all perpetual revenues which do not come under category 1. This is equivalent to a rate of 15 per cent., increased in all the categories by two centesimo per cent. to cover expenses of verification and collection. (3) Income is reduced to 20-40ths in this category, which consists of incomes derived from the co-operation of capital and labour, *i.e.*, those produced by industries and commerce. The rate is therefore 10 per cent. (4) Income is reduced to 18-40ths when derived from labour alone (private employment) and those represented by temporary revenues or life annuities. The rate is therefore 9 per cent. (5) The income is reduced to 15-40ths in the case of salaries, pensions, and all personal allowances made by the State, the provinces, and communes. The rate is 7½ per cent. The average rate of the tax works out at something like 12 per cent. Incomes under categories 3, 4 and 5, not taxed at the source, and which do not exceed £16 after the reductions have been made, are exempt from taxation. No minimum is exempt under categories 1 and 2. The Spanish tax is remarkable in that "the scale of taxation on property is, as a rule, lower than that on personal exertion." Unearned incomes and mixed incomes are taxed at rates varying from 20 per cent. down to ½ per cent. in a manner designed to be roughly proportionate to the profits of specific enterprises; on the other hand the earned salaries and pensions of State officials and of generals in the army are taxed, not universally at the lowest rate as in Italy, but at the high rates of 20 per cent. and 18 per cent. Relief, therefrom, is however, afforded for smaller incomes of this class by graduation, and the graduation is such that the poorest incomes of the class (£30 to £45) pay only two per cent. instead of the full rate of 20 per cent. and 18 per cent. Earned incomes from commercial and other civil occupations are taxed at one of two rates—10 per cent. and 5 per cent. A whole class of earned incomes, however which in Italy falls under the income tax is omitted altogether from the scope of the Spanish tax on "incomes from personal property." While the profits and *employés* of banking, railway, and insurance companies, and indeed of public companies generally, are included in it, ordinary individual trading and professional incomes are taxed under an older and quite different law, that of the tax or the "exercise of industrial, commercial, and professional enterprise." This tax, being based on the character of the business and the population of the locality in which it is carried on, is analogous to the French "Loi des Patentes." It is an "industry" tax not an income tax.

In Russia an earned income of £56 pays ·67 per cent., an unearned pays in all 1·92 per cent.; an earned income of £150 pays 2 per cent., an unearned pays in all 3·25 per cent.; an earned income of £500 pays 3 per cent., an unearned pays in all 4·25 per

cent.; an earned income of £5,000 pays 4 per cent., an unearned pays in all 5·25 per cent. In Saxony the differentation is almost identical with that of Russia, in Wurtemberg it is greater in the proportion roughly of 8 to 5. In Denmark an unearned income of from £166 to £222 is taxed twice as heavily as the earned income of that amount. For lower incomes (down to the limit of exception) the differentiation is slightly greater, for higher incomes it becomes less, the rate of an unearned income of £5,550 or over being only 1·6 times the rate for a corresponding earned income. In the Netherlands and Bavaria there exist separate graduated taxes, the one affecting earned income only, the other affecting unearned income only. In the Netherlands the rate for a pure industrial income is less than that for a pure unearned income of the same amount in a fixed proportion of (approximately) 3 to 5. For mixed incomes, derived partly from labour and partly from property, there is a special arrangement, the earned portion of it being taxed more heavily than a pure earned income of the same amount unaccompanied by income from property. As in most other countries, so in Switzerland, the differentiation is most marked in the case of the smaller incomes. For an income of £40 the least differentiation is found in Valais and the greatest in (if Bâle-ville be excluded) Uri, where an unearned income of that amount is taxed no less than 16·67 times more heavily than a corresponding earned income. For an income of £400 the least differentiation is in Grisons, where the proportion is 118 to 100; in Bâle-campagne the differentiation is the proportion of 412 to 100. For an income of £4,000 the greatest differentiation is in Bâle-campagne, where an unearned income of that amount is taxed 4·12 times more heavily than an earned income. On the other hand, in the Grisons an exceptional application of the principle of differentiation involves the taxation of an income of £4,000 higher if earned than unearned. The rates here contrasted are those applicable to pure labour incomes and pure property incomes respectively. As such they represent the extremes of the differentiation. There is, of course, a large class in every community possessing a "mixed" income.

Three different methods of assessment and collection are exemplified in the Reports—(1) that of assessment on the declaration of the individual taxpayer; (2) assessment by the taxing authority from such information as it is able to obtain without compulsory declaration; (3) assessment, where possible, of the income in the hands of its first possessor, or collection "at the source of income," with the right of deduction, as understood in this country. Compulsory declaration is the general rule in Germany, Switzerland, the Netherlands, Sweden, and Denmark; assessment by the taxing authority in some of the Swiss Cantons and in Norway; assessment at the source in Austria and Baden. In the latter, for instance, it is applied to the salaries of minor State officials, and to the workpeople employed by large contractors, who pay and deduct the tax on wages. In Austria, "fixed salaries" and wages where the tax is collected from the *employés*, are also taxed at the source. A more important instance is the assessment of companies to income tax, a usual feature in foreign income taxes. When the profits of a company or corporation are taxed like those of an individual, and the dividend for distribution thereby diminished, the tax must be held to fall upon the latter, who, when they are also obliged to return the amount of this dividend with the rest of their income for assessment, may be taxed twice over for this portion of it. Double taxation of this kind is obviated in Norway, where the taxpayer is not personally assessed on the income he derives from companies, and in Hesse, where in making his return of income he deducts income derived from profits distributed by companies. In other States some partial exemption is made to mitigate the double taxation which would otherwise occur. In Prussia, Baden, and Sweden, for instance, only the profits of a company over a certain fixed percentage of the capital are subject to the tax. In Saxony, however, no provision of this kind is to be found. In Italy, the assessment of incomes from private industries, trades, or professions or from companies with unlimited liability, is on an average of two years, in all other cases it is on the income of the current year, or, as in the case of limited liability companies, on the basis of the accounts closed before the previous July of the current year. Collection is generally in the hands of the State or local officials paid by fixed salaries. Italy and Spain, hower, afford exceptions. In Italy there are collectors (for the communes) who collect the sums owed from the *employés*, and send them forward to the provincial Receivers (for the provinces), who also receive a percentage, and pay the income tax to the State. In Spain, the tax is collected by the same officials charged with the collection of other taxes.

SUNDAY TRADING.

There is a general impression that Sunday trading is on the increase, but probably few have any idea of the extent to which it has grown in recent years. The evidence taken by the Select Committee of the House of Lords on the Sunday Closing (Shops) Bill, and just published, is conclusive as to the growth of this trading. In London it is found more especially in districts largely inhabited by Jews, such as Whitechapel and Stepney, but in great provincial towns like Liverpool, Manchester, Belfast, Glasgow, it seems to be general. In his evidence before the Committee, Mr. Edwin Openshaw, chairman of the Manchester and District Meat Retailers' Association, said that within a radius of 12 miles of Manchester, from a rough estimate taken, there are some 15,000 shops open, and some 25,000 people employed in these shops of all classes, and the vast majority of them would be glad to close on Sunday, provided

they all closed. Taking Manchester and Salford only, Mr. James Kendall, the secretary of the Manchester, Salford, and District Grocers' Association said that in order to ascertain the amount of Sunday trading the whole area was divided into some 50 districts, that on two given Sundays these districts were canvassed, and it was found that 6,498 shops were open on that particular day. It was not a complete canvass because one of the districts was not canvassed. Not only has the number increased, but the system on which the business is carried out is very different to what it was ten or twenty years ago. Then the shopkeepers did their business in a sort of apologetic way; they left the door on the latch, then they opened the door, then they pulled the shutters down. "Now," says Mr. Kendall, "We have a shop in Manchester, a butcher's shop, where six men are employed all Sunday morning, where meat exposed outside on the pavement, and where, on the Sunday that the canvass was taken, at one time there was no less than between 50 and 60 customers." On the day of the canvass, in a triangular area of not more than half a mile on each side, 171 shops, excluding 42 licensed premises, were open for business on the Sunday morning, and doing a thriving trade. That is in a working-class district, where all the men receive their wages at noon on Saturday, this volume of Sunday trading was going on, not because the working man cannot accommodate himself to it, but because it gives him a Saturday afternoon for pleasure and relaxation, and he knows he can get his stuff on Sunday morning, and it makes him indifferent whether he shops on Saturday or not.

It is much the same in Liverpool. A report as to Sunday trading was taken at the instance of the Watch Committee by the police, with the following result:—The number found to be open was between 4,000 and 5,000; 25 per cent. were sweet shops, and were open all day. The herb beer and refreshment shops numbered nearly 500. Tobacco and stationery accounted for another 1,000, and these show an increase of about 100 in the afternoon. Then there were grocers, greengrocers, and butchers, and they represent slightly over 1,000. They were open in the morning. They dropped down 50 per cent. in the afternoon, the number of butchers dropping from 205 to 22. Then the milk dealers—540 in the morning and 467 in the afternoon. The barbers were 109 in the morning and 13 in the afternoon; street vendors, 199 in the morning and 128 in the afternoon. With the exception of tobacconists and paper shops, there is a decrease after two o'clock. The shops open in the afternoon were less than two-thirds of the morning number, 3,908 in the afternoon and 4,581 in the morning. And as in Manchester, the old sense of wrong-doing seems to have disappeared. "We find," said Mr. J. Charles, President of the Liverpool Tradesmen's Conference, "that the number of Sunday sellers is increasing, and not only that, but they are opening now without any fear or sense of shame or decency. The shops are open, the shutters are down, and the trade is carried on on Sunday the same as any other day of the week."

The experience of Belfast is similar. "Including spirit grocers," said Mr. T. G. Perry, President of the Belfast and North of Ireland Grocers' Association, "and the general traders that open on Sunday, we have about 1,000 places on Sunday, either for the whole day, or part of the day, engaged in trade." But perhaps the most remarkable illustration given of the growth of Sunday trading was furnished to the committee by the figures submitted by Mr. Kenneth M. Milligan, Chairman of the Scottish Shopkeepers' and Assistants' Union. The total number of shops in Glasgow, as given by Mr. Milligan, that are occupied is 16,651, and the total number open on the Sabbath day is 3,040. Sunday trading is increasing from year to year. It is curious, that of the 3,040 shops open in Glasgow on Sunday only four are those of barbers. The greatest increase has been among shops for the sale of aerated waters, sweetmeats, ice cream shops, and all the other class of shops of that kind.

The figures given above show that the growth of Sunday trading in the great provincial towns has been very large. In London, in certain districts, it is much larger, but it seems to be less diffused, and more attributable to the presence of large numbers of Jews. This is particularly the case in Whitechapel and Stepney. In his evidence, the Rev. Alfred Poynder, Vicar of Whitechapel, told the Committee that "between 30,000 and 50,000 on a Sunday morning, who are not of the alien population, do their shopping in our streets, and crowd our neighbourhood right up till noon, practically converting the whole of the morning into an enormous fair. We have hat shops, boot shops, clothing, and other kinds of shops open. The British population say they would lose their custom in a great measure if they in self-defence did not open on the Sunday." Mr. Douglas Eyre, who has been Resident at the Oxford-house, Bethnal-green, for many years, and is now Vice-Head of the House, said that Sunday trading has increased to an enormous extent in that area during the last few years; a great number of the stall holders are not Bethnal-green traders at all, but come from other boroughs where such trading is not allowed. They often bring with them food stuffs which they have failed to sell in other markets, and the borough is discredited by the amount of stolen property in the market, and by the persons of undesirable character which such trading attracts. In no part of London can such a concourse of people be found, says Mr. Eyre, as that gathered together in Bethnal-green on Sundays between the hours of 10 and 2. They come from all parts and portions of the district of Bethnal-green and of Spitalfields, and constitute a regular Sunday fair. "In Bethnal-green there is a great deal of selling of meat and vegetables going on till after one up to almost two o'clock. There is a great trade in cycles, and it is the recognised place in East London for anybody to go on Sunday

who requires a new tyre to be fitted to his cycle. There is an extensive market for the sale of dogs, conducted by labouring men as well as ordinary professional dog sellers. Then there is a large amount of trade in the quack doctor line—pills, and things of that kind, and quack medicines. There is a big trade in birds of all kinds, pigeons and fowls, parrots and canaries. In Middlesex-street there is an immense sale going on in old clothes, watches, trinkets, race cards." "The mass of people," says Mr. Eyre, "gathered together at the top of Bethnal-green is such that it is very difficult for omnibuses and others at some parts of the Sunday to pass down the road at all. They are obliged to go at a very slow walking pace."

The vicar of St. Mark's, Walworth, the Rev. Francis Forster, speaks of a very similar district in his own parish—East-street, Walworth, close to his church—where a market very similar to the Petticoat-lane market exists. There is an enormous influx on the Sunday from all parts of London into the street, both as buyers and sellers, and a very large trade done mostly in the non-necessaries of life, such as poultry and birds, toys and old clothing, and there the small shops, the greater part of the street consisting of them, keep open in defiance of the costermongers. Sunday is under these circumstances a day on which a very much larger amount of business is done than on any other day of the week. In the main roads of Walworth there is not much Sunday trading, and what there is is almost conclusively confined to sweet shops, and ginger-beer shops, and fruiterers.

The Committee are convinced by the evidence not only that Sunday trading is very largely on the increase, but that an Act for restricting it is urgently needed and desired by the shopkeeping interests. Moreover, that such an Act would not inflict serious hardship on the poorer classes if due regard were had to certain necessities, which might be met if the Local Authority, with the consent of the Secretary of State, was able to exempt particular areas from the provisions of the Act if in its judgment, owing to any special circumstances, it would press with undue and exceptional severity on the general body of the traders and their customers within the district. Of course the difficulty in places like the Metropolitan districts mentioned above is that the trade is very largely in the hands of Jews, who are not allowed by their religion to trade before sundown on Saturday, and as a matter of practice are accustomed to use the hours after sundown on Saturday for the purposes of recreation. This point was put by Mr. Abraham Valentine, who spoke as the representative of the Costermongers' Street Sellers Union,—"The Jewish people," he said, "generally take their recreation on Saturday nights, when their Sabbath terminates. I myself am closed during the year as follows:—Fifty-two Saturdays, fifty-two half-days (Fridays). There, perhaps, I may make a little correction. In the summer time on the Friday it would vary from about 5 o'clock to about 7. In the months of June and July we could keep open till 7 o'clock, but in the winter time we should close, certainly at half-past three. . . . The compulsion would be directed against the Jews only, for the Christians can get their six days' labour without working on their Sabbath." The answer would be, as pointed out by members of the Committee, that in opening on Sunday the Jew is breaking the law of the land in which he lives, and driving his Gentile neighbour to open on the Sunday. As to the law as it stands, the Act of Charles II., there was general agreement among the witnesses that it is not deterrent. It imposes a tax of 5s. only, which is absolutely inadequate, and there is much prejudice and popular feeling against putting it into operation. For the purpose of prosecuting Sunday traders one particular portion of the Act has to be selected. It also enacts that any person who does not go to church or chapel on Sunday shall be punished and fined equally, and it is objected that if one part of the Act is treated as obsolete, it is invidious to put the other into force. However that may be, the Committee are of the opinion that a more stringent law passed in these days would adapt itself specially to deal with the evil, and they have reported that in their opinion Lord Avebury's Bill "would be a great benefit to the country generally, and commends itself both to the reason and the conscience of the community."

FOREIGN TRADE OF INDIA.

In his exhaustive report on the foreign trade of India for the official year ending March 31st last, Mr. J. A. Robertson, late Director-General of Statistics to the Indian Government, explains in detail the bearing of the figures on this subject which were published in June. The imports of merchandise during the year amounted to £64,450,000, compared with £56,548,000 in the year preceding, while there was an advance in the value of the exports from £99,756,000 to £102,751,000. In 1903-4 the export trade received an abnormal stimulus owing to the exceptional demand for and high price of raw Indian cotton, while the imports were influenced in the opposite direction consequent on the partial paralysis of the Lancashire cotton industry, due to the shortness of the American supply, which resulted in a great decrease in the importation of cotton manufactures into India. In 1904-5, on the other hand, the extraordinary abundance of American cotton brought with it exceptional prosperity for the Lancashire mills, and the revived Indian demand for cotton goods exceeded all previous records. Imports of cotton yarn and fabrics in 1904-5 thus increased in value by 22·7 per cent., while the exports of raw cotton fell by 28 per cent. The importation of other textile goods was also beyond precedent,

the total Indian purchases of all yarns and textile fabrics reaching the sum of £29,053,000, representing 45 per cent. of India's total imports of merchandise. The expansion of the import trade, moreover, was general, and on this head Mr. Robertson remarks:—"The value of the imports of mechandise in 1903-4 was greater than in the preceding year by 603·5 lakhs (£4,023,000), or 7·6 per cent., and in 1904-5 there was a further advance of 1,185.5 lakhs (£7,903,000), equal to 14 per cent. So large an increase as 1,789 lakhs (£11,926,000) in two consecutive years is unrivalled, and no other year has witnessed quite so large an absolute increase as 1904-5, though it was approached by the increase of 1,057 lakhs (£7,046,000) in 1880-1, in which year a brisk revival of trade marked returning prosperity after a period of widespread distress and famine, and almost equalled by an advance of 1,135 lakhs (£7,566,000) in 1893-4), when the temporary stimulus to imports given by the closing of the mints on the introduction of the currency reform raised their value far above that attained in any of the seven succeeding years." How remarkable has been the progress of the Indian import trade is shown by the fact that although 1880-1 was exceptionally prosperous, the total for 1904-5 was 92 per cent. greater than in that year; in other words, the imports almost doubled in the course of a quarter of a century.

The export trade was marked by the decrease in raw cotton, already mentioned, but, on the other hand, the shipments of wheat, rice, and other food-grains were unparalleled. The wheat exports increased in value by 698 lakhs (£4,653,000), and those of all grains by 851 lakhs (£5,673,000), while as regards quantity the total shipments of wheat reached 43,000,000 cwts. compared with 25,911,000 cwts. in 1903-4, and 10,292,000 cwts. in 1902-3. Of the wheat exports last year 67 per cent. was shipped to the United Kingdom. The estimated yield for the present season is, owing to the unusual circumstance of severe frosts, one-fifth less than that of a year ago, but there will still be a large surplus for export. Estimated by value, the shipments of raw jute, raw skins, raw wool, cotton manufactures, jute manufactures, and lac in 1904-5 were the largest on record, while the quantities of tea, coal, and seeds were larger than in any previous year. Spices, indigo, vegetables, raw silk, and dressed skins, however, recorded a decline.

An examination of the details of the import trade shows that larger purchases of sugar, machinery, raw cotton, and textiles were mainly responsible for the increase in the various classes into which the imports are divided. A decrease in the purchases of oils has been continuous for three years past, and is due to the increasing consumption of indigenous mineral oils refined in Burma and Assam. The expansion in the imports of sugar is very remarkable, the total quantity taken last year amounting to 6,549,797 cwts., compared with 6,038,115 cwts. in the year preceding, and 4,987,195 cwts. in 1902-3. Beet sugar rose in quantity from 552,737 cwts. to 1,716,488 cwts., while there was a decrease in the imports of cane sugar from 5,485,378 cwts. in 1903-4 to 4,833,309 cwts. in 1904-5. Java now occupies first place in the Indian sugar market, the quantity received from that source during the year being 2,546,000 cwts., or 38·9 per cent. of the total imports. The tariff preference given by the United States to Cuban sugar, and the recovery of the sugar industry in that island, had deprived Java of its assured position in the American market, and in 1903-4, when shipments to the United States declined, a portion of the crop was diverted to India. In 1904-5 the Java crop was exceptionally large, and the shipments to India increased simultaneously with large purchases by American refiners. Austria-Hungary contributed 1,441,240 cwts. of beet sugar as compared with 299,259 cwts. in 1903-4, 880,018 cwts. in 1902-3, and 2,257,928 cwts. in 1901-2, when abnormal shipments were made in anticipation of the additional countervailing duties. The subsequent decision of the Indian Government not to maintain countervailing duties against any country which is a party to the Brussels Convention resulted in the revival of the imports from Austria-Hungary indicated by the figures quoted. Imports of sugar refined in the United Kingdom, on the other hand, fell from 637,277 cwts. in 1903-4 to 121,348 cwts. in 1904-5. This trade, which has so largely decreased, was the outcome of the advantages conferred upon cane sugar by the repressive legislation directed against the introduction of the bounty-fed article, and its diminution is due to the withdrawal of the restrictions by the Indian Government.

In the imports of hardware and cutlery there was, last year, an increase of about 3 per cent., bringing up the total increase for the past ten years to 87 per cent. The United Kingdom's share of this trade is equal to 64·7 per cent., while that of Belgium and Germany combined is 18·5 per cent. The imports of copper fell by 1·3 per cent. in quantity and 2·7 per cent. in value, the rise in price having checked this trade. Iron showed an increase of from 232,570 tons to 257,580 tons, but steel decreased from 226,335 tons to 211,581. It is intimated, however, that the distinction drawn in the statistical returns between common bars, plates, and sheets of iron and steel respectively is not wholly trustworthy. Of India's imports of these manufactures last year, 65·8 per cent. in quantity and 65 per cent. in value came from the United Kingdom. The value of the machinery and millwork imported reached the unprecedented total of 402¾ lakhs (£2,685,000), which is nearly 15 per cent. above that of the previous record. The imports of railway material, on the other hand, showed a slight decrease as compared with 1903-4, which was a record year. Kerosene oil decreased to the extent of 2·6 in value, although the imports increased by 6 per cent. in quantity. The Burma Oil Company, which monopolises the Burma oil trade, is, Mr. Robertson states, rapidly expanding its business, and with the projected increase of £1,000,000 will have an authorised

capital, including debentures, of £3,000,000. As regards coal there was an increase of 40 per cent. in the quantity imported, this being attributed to excessively low freights and the depression in the British coal trade. The total of private imports was 252,400 tons, while the production of Indian coal in 1904 reached 8,212,000 tons, an advance of 10 per cent. on the previous year. The division of the import trade among the principal countries in the past five years was as follows :—

	1904-5	1903-4	1902-3	1901-2	1900-1
1. United Kingdom	65·2	64·9	66·3	64·5	63·8
2. Austria-Hungary	4·1	2·6	3·2	4·8	4·1
3. Germany	3·9	3·4	2·7	3·7	3·4
4. Belgium	3·6	3·9	3·9	3·7	3·2
5. Straits Settlements ...	3·2	2·9	2·9	2·9	3·0
6. Java	2·1	1·4	0·7	0·5	0·3
7. Mauritius..................	2·1	3·1	2·5	2·4	3·2
8. China........................	2·0	2·3	2·8	2·2	3·3
9. France	1·9	1·9	1·8	1·7	1·4
10. Russia	1·7	2·9	3·4	3·9	3·7
11. Japan	1·2	1·5	1·0	0·87	1·1
12. United States............	1·1	1·5	1·5	1·4	1·6

The above does not include Government stores, of which 94 per cent. in 1904-5 came from the United Kingdom.

The net addition to India's stock of gold in 1904-5, including the local production, was £8,837,431, compared with £8,963,000 in the year preceding. The exports of gold by the Government, amounting to £5,605,000, included remittances to London of £4,500,000 for the purchase of silver, and £1,000,000 for investment in gold securities on behalf of the Gold Reserve Fund. Owing to a mistaken calculation the figures relating to silver imports and exports were overstated in the report for 1903-4. The actual net imports for that year amounted to £9,033,000, which compares with £8,915,000 in 1904-5.—*The Economist.*

NINGPO VARNISH.

The United States Vice-Consul at Hanghchau calls attention to what is known among foreigners in China as "Ningpo varnish," made from the sap of the varnish tree (*Rhus vernicifera* or *Vernix vernicia*) which grows very extensively in western and south-western China. The name was originally given because varnishers from Ningpo were more skilled in its preparation and use than others. The sap is gathered in the interior and brought to Huichoumin, in the southern part of Anhui Province, where it is refined and then distributed to all parts of the Empire. It is sold by the retailer in the raw or pure state—that is, the pure refined sap, and in the prepared form, which is a mixture of the refined sap with certain proportions of "wood oil." It is in the proper blending of these that the skill of the varnisher is shown, as the colour desired, the wood to be varnished, moisture of the atmosphere and temperature are conditions that enter into the problem. The uses of the varnish are manifold. Wherever varnish is desired the Ningpo kind is used, and is so far superior to the ordinary varnish of commerce as to be in a class by itself. It is particularly adapted to floors, tables, cabinets, and such articles as are in constant use. It is also excellent for furniture of all kinds, as it does not scar easily, and may be scrubbed with boiling water without the slightest injury to the very high polish of which it is capable. The greatest drawback to its use is the danger of "lacquer poisoning" to the workmen who use it. This is similar to "ivy poisoning," and when the sap is fresh is regarded as rather dangerous. Once the varnish is dry there is no danger whatever. It may be used in any climate that has a rainy season or wet weather. The varnishing is always done during the wet season and is allowed to dry slowly as the moisture of the atmosphere decreases. The market value of the pure sap after refinement is about 2s. 2d. English money, per catty (catty = 1⅓ pound avoirdupois), while the mixed varnish may be had for about 1s. 1d. per catty. It may be mixed ready for use before shipment and does not deteriorate when once it has been properly blended. Something like a hundred years ago the Ningpoese had a monopoly of the varnish trade, but in some unaccountable manner they lost it to the Huichau firms. Practically all the varnish used at the present time comes from Huichau as its monopoly depends on a knowledge and skill which the Huichau people seem to be able to guard most effectually. The supply of this crude sap would seem to be unlimited, as the trees from which it is derived are found in great abundance in all the middle western and south-western provinces. With proper methods of gathering the sap and of refining, it should, it is said, be made one of the most profitable industries of China.

GUATEMALAN COFFEE.

Shortly after 1860, coffee-growing began to take the place in Guatemala of the cultivation of the indigo and cochineal plants that had been grown there for many years previous to the discovery of the chemical dyes that are now the colours known to the commercial world. From that time until recently, the business gradually grew, until in 1902, the coffee crop exceeded 74 million pounds of clean coffee. Only a small portion of the area of the country is adapted to the cultivation of coffee. At present good Government coffee lands are very scarce, but when found can be had for about 1s. 3d. to 1s. 8d. per acre, and when brought under cultivation with a good stand of trees, are worth from £20 to £100 or more. The coffee of commerce grows in altitudes of 1,000 to 6,000 feet; the best and most prolific trees at 2,000 to 4,000 feet. The labour is cheap, from 1½d. to 10d. a day. The industry as yet has not been brought to a very high

state. Only in a few cases has an effort been made to crowd the coffee trees to see what they could be made to do. Guatemala coffee is rated very highly in the markets of the world, and is the principal industry of the country, it giving employment to more than one-half of the population for about half of the year, during the harvesting time.

GENERAL NOTES.

TRADING RIGHTS IN FRANCE.—In his Report on the Trade, Commerce, and Agriculture of the Consular District of Calais for 1904 (No. 3346, Annual Series), Mr. Consul Payton refers to a very important decision of the French Courts. A British limited liability company, the registered name of which indicated the nature of the business, had for many years manufactured in Boulogne and traded under the British name, usually adding its French translation. A French "Société Anonyme," formed long afterwards, sought to debar the use of the French translated name, pleading that it constituted unfair competition, because customers might be induced to believe that they were dealing with a French company. The Boulogne Court adopted this view, and awarded damages against the British company; but the Court of Appeal at Douai has reversed this judgment, and decided that an alien company, legally trading in France, has full right to make the nature of its business clear to prospective customers by using a French translation concurrently with the name under which it may be registered, but such French name must not be used alone. There are in France many British businesses trading under their French translated name, and if the judgment of the Boulogne Court had not been reversed on appeal it might have seriously affected those firms trading in France in accordance with the Convention of April 30th, 1862, relative to joint stock companies.

HOURS OF LABOUR ABROAD.—It is often complained that the greater latitude in the matter of hours of labour allowed by foreign Governments handicaps British industry. Be that as it may, foreign employers are not always satisfied with the time limits of labour as they affect themselves. For example, the fish curing and fishp reparing industries of Germany complain of the restrictions to which they are subjected, in that they are precluded from employing women beyond the prescribed hours, viz., 8.30 p.m., and 5.30 on Saturdays. Mr. Vice-Consul Oliver reports that although men are allowed to work overtime excepting on Sundays and public holidays, and the local authorities are able to modify these regulations to some extent, it is sought to obtain powers to employ women on a certain number of days in the year after the regulation hours in order that the fish may be dealt with immediately upon its arrival. The present regulations fix the day for women workers at 11 hours, and for Saturdays at 10 hours, but an exception is made in the case of the vegetable preserving industry, and the same privilege is thought to be equally necessary in the fish-curing establishments. The latter claim that they should be able to employ women between the hours of 5 a.m. and 11 p.m. for an 11 hour day, and during 40 days in the year for a 13 hour day.

BRITISH TRADE WITH FORMOSA.—In reviewing the trade of South Formosa for 1904, Mr. Consul Wileman (No. 3490, Annual Series), whose report is dated June 29, 1905, says that there promises to be a good demand for machinery, principally for sugar mills, and the British machinery catalogues might be advantageously re-cast. In many instances these catalogues are issued only for the use of practical engineers, or for persons having a high technical knowledge, and do not compare favourably with American catalogues, which cater for farmers, contain much fuller and simpler details, and are easier of comprehension to the lay mind. It seems desirable that British machinery manufacturers should endeavour to improve their catalogues in a way calculated to remedy this defect, and to adapt them to meet two conditions, firstly for new markets like Formosa, where machinery is but rarely employed, that is to say for districts where the essential points to be considered are moderate prices and simplicity of construction and design, and where too many technicalities are to be deprecated on account of a possible lack of technical knowledge on the part of buyers: and secondly, catalogues for advanced markets, which should contain full technical details of highly-finished or expensive machinery for the use of practical engineers and persons acquainted with the technicalities of machinery. Mr. Wileman thinks that motors will have a good future in Formosa, but only those which are simple and easy of transport. Strong, light carts, with tyres adapted for use in very rough country, will also find a ready sale, provided that samples are actually shown on the spot working in a serviceable manner.

RÉUNION.—The island of Réunion seems to be in a sad case. Last year a cyclone destroyed 50 per cent. of its sugar, and 75 per cent. of its vanilla crops, and another cyclone last March seriously damaged the plantations. Trade with Mauritius has ceased since the outbreak of plague, except for the importation of a certain amount of machinery for sugar mills, and quarantine restrictions have been in force since January. The only share in the commercial life of Réunion, such as it is, possessed by British traders, is the importation of rice from India, and that, together with some rice from Saigon, is carried by about a score of British ships annually. Mr. Consul Maxse (No. 3498, Annual Series) states that if the price of sugar is maintained at its present level, and labour is got for the sugar estates, a little trade with the United Kingdom and British Colonies may spring up, but at present such trade does not exist, and there is no likelihood of its becoming important.

Journal of the Society of Arts.

No. 2,760. VOL. LIII.

FRIDAY, OCTOBER 13, 1905.

NOTICES.

EXAMINATIONS.

The Programme for 1906 is now ready. The price of the Programme (containing the previous year's papers and the examiners' reports on the work done) is 3d. Copies can be had at this price on application to the Secretary, Society of Arts, Adelphi, W.C.

The Examinations in Commercial Knowledge are now arranged under the following stages:—Stage I.—Elementary; Stage II.—Intermediate; Stage III.—Advanced.

The Examinations will commence on Monday, April 2, 1906. The last day for receiving entries is February 28th.

Examinations are also held in the Theory and in the Practice of Music, and Vivâ Voce Examinations in French, German, Spanish, Portuguese, and Italian.

PRIZES FOR INDUSTRIAL DESIGN.

The Council of the Society of Arts hold a sum of £400, the balance of the subscriptions to the Owen Jones Memorial Fund, presented to them by the Memorial Committee, on condition of their spending the interest thereof in prizes to "Students of the Schools of Art who, in annual competition, produce the best designs for Household Furniture, Carpets, Wall-papers, and Hangings, Damasks, Chintzes, &c., regulated by the principles laid down by Owen Jones."

The prizes will be awarded on the results of the annual competition of the Board of Education, South Kensington. Competing designs must be marked "In competition for the Owen Jones Prizes."

No candidate who has gained one of the above prizes can again take part in the competition.

The next award will be made in 1906, when six prizes are offered for competition, each prize to consist of a bound copy of Owen Jones's "Principles of Design," and the Society's Bronze Medal.

PROCEEDINGS OF THE SOCIETY.

THE EXAMINATIONS OF 1905.

For many years past it has been the practice to include in the Annual Report of the Council a summary of the results of the Society's examinations. But this year the number of candidates has become so large that it was not possible to prepare the usual detailed review of the results at the time when the Council Report was issued. The results, however, have now all been published, and it is possible to examine the effects of the recent changes in the examination system. These changes have been so often set forth in the *Journal*, as well as in the Examination Programme, that it does not appear necessary to describe them again. It may be sufficient to mention that the principal alteration was the substitution of three Stages for two, thus enabling the Council to comply with the suggestions that had often been made to them that an examination of a character somewhat more advanced than hitherto should be provided.

It is satisfactory to be able to report that the changes appear to have met with the approval of all who are interested in the examinations. The best proof of this is the large additional number of candidates, and since the holding of the examinations many expressions of appreciation of the alterations have been received from the representatives of the Local Examination Committees.

The total number of candidates at the examinations held in April last, was 21,253 (Advanced, 4,278; Intermediate, 9,578; Elementary, 7,397). This is an increase of 3,482 upon the 17,771 candidates of 1904. The number of papers worked by these candidates was—Advanced, 4,844; Intermediate, 9,993; Elementary, 8,427. In addition to this there were 540 candidates examined in Music at the same time as those in the Commercial subjects. In addition to these again there were 681 candidates in Colloquial Modern Languages, and 418 in the Practice of Music. The total number of candidates who were examined in all subjects by the Society of Arts during the year ending July last, was therefore 22,352.

The general growth of the examinations is shown by the diagram on page 1110. This diagram, which deals with round numbers only, commences with 1883, and ends with the present year. It will be seen that in the 23 years dealt with, the numbers have increased from 800 to 24,000. In the first ten years the increase was moderate, though steady, for the numbers reached 4,600. From that date the growth was rapid, for in five years the numbers had reached 7,600, and in five years more this number had been more than doubled—16,200. It may be mentioned that these totals include the results of the written examinations in Music, but not those of the *vivâ voce* examinations or of that in the Practice of Music.

The detailed results of the 1905 examinations, which were held at 383 centres, are shown by the table on page 1111. This table shows the number of papers worked in each subject in each Stage, and the number of successes and failures. Exact comparison with the work of previous years is precluded by the alteration in the system. It may, however, be noted that the total number of candidates in the Advanced and Intermediate Stages show in every subject, except Italian and Spanish, an increase on the numbers entering for the corresponding subjects in Grade II last year. In Spanish the numbers are the same—174. In Italian there were this year 33 candidates, whereas last year there were 38. This trifling deficiency is more than accounted for by the fact that Italian has been added as a subject in the Elementary Stage and that there were 22 entries for it. In some subjects the increase is very slight—Commercial History and Geography, 102 against 98; Economics, 81 and 79. But in others the increase is very large. Book-keeping is still, as always, the most popular subject, and heads the list with 5,768, against 4,893 last year. Shorthand comes next with 4,353, compared with 3 910; then Typewriting, 1,308 and 1,044. Précis-writing has almost doubled its numbers—209 and 106; and Arithmetic shows a satisfactory increase—514 against 345. The same may be said of English with 318 against 258. All the modern languages (except the two previously mentioned), show an increase—French, naturally the largest, 1,098 compared with 805; while German follows with 442 against 318. Spanish comes next with 174 in both years, while the numbers of the other languages are naturally smaller, with a small proportionate increase—Portuguese 34 and 29, Russian 17 and 11, Danish 4 and 2. Italian alone, as above stated, shows a falling off, 33, compared with 38. It is satisfactory to note that of the additional subjects added this year, two attracted a substantial number of candidates—Commercial Law 169, and Accounting and Banking [illegible] Hindustani, which was also added this year, only attracted two candidates. It is hoped that this may be improved in future years. Japanese has been on the list for a long time, but this was the first year in which an examination was held, three candidates having entered for it.

PERCENTAGES OF SUCCESSES AND FAILURES. ADVANCED STAGE.

	First-class.	Second-class.	Failures.
Arithmetic	31·82	35·06	33·12
English	7·23	54·22	38·55
Book-keeping	14·02	54 63	31·35

Russian	10·00	60·00	30·00
Hindustani	50·00	0·00	50·00
Japanese	0·00	33·40	66·00

The manner in which the various subjects were dealt with may be estimated from the preceding tables which show the percentages of failures and successes in the two upper stages. The number of entries in some of the smaller subjects is insufficient for such calculations to have much value, but the percentages are given for the sake of completeness.

In the Elementary Grade the 7,397 candidates worked 8,427 papers, so that a large proportion of the candidates in this, as in the higher grades, were content with a single subject. Book-keeping attracted the largest number, 2,649, and there was an increase of 364 on the 2,285 of last year. The subject, however, showing the greatest increase was Shorthand, for there were 411 more than in 1904, 2,230, against 1,819. The next largest subject was Typewriting, for which 1,044 candidates presented themselves in 1905, and 914 in 1904. In Handwriting and Correspondence there were 532 this year, and 371 last; in Arithmetic 621 and 577. In French the numbers were 851 and 828, in German 315 and 252 (a good proportionate increase), Spanish 67 and 25 (the largest proportionate increase of any). In Commercial Geography alone was there a falling off, for only 96 candidates entered, whereas last year there were 132. Italian, a new subject in the Elementary Stage, attracted 22 entries.

The general percentages of success and failure work out as follows: — Advanced, First-class, 14·2; Second-class, 51; failures, 34·8. Intermediate, First-class, 17; Second-class, 50·4; failures, 32·6. Elementary, successes, 57; failures, 43. With regard to Stages III. and II., these percentages may be looked upon as about normal. Last year, when there were three classes, the percentages were:—First, 13·4; Second, 28·7; Third, 33·9; failures, 24. It is evident that in both stages a few of the old Second-class have been admitted into the First, while the bulk of the Third have passed into the new Second, the remainder having dropped down among the failures. This is very much what might have been expected, and shows that the standard aimed at has been successfully attained by the Examiners. It appears certain that a good many of the candidates who attempted the Advanced Stage were a little too ambitious, and would more wisely have been satisfied with the Intermediate. The advice may safely be repeated, that candidates entering these examinations for the first time should content themselves with Stage II., unless they are advised by competent authorities that they are sure to succeed in Stage III. A First-class in Stage II., followed by a First-class in Stage III., is a far more valuable record than a Second-class in Stage III., though it be obtained the first time of asking. In future years a slight elevation of the Advanced Stage may fairly be looked for, but no attempt to raise it will be made next year. It is not to be expected that any change of standard will be made in the Intermediate Stage.

As regards the Elementary Examinations, a comparison with the work of previous years is possible, because in this Stage no alteration has been made. The percentage of successes (57 to 43) compares rather unfavourably with last year, when 61 per cent. passed and 39 failed. It is quite evident that the increase of numbers from 7,203 in 1904 to 8,427 in the present year has been accompanied by a slight falling off in the qualifications of the candidates, a proportion of whom certainly enter without such training as justifies them in expecting to pass even an examination of such a very simple character as the Elementary. That this is the case is evident from the fact that the proportion of failures shows an increase in nearly all the subjects, except French, in which the standard was designedly lowered, and in Spanish, in which the numbers are hardly large enough to form a basis for generalisation. It is, however, not so much to the language subjects that the above remark applies, as to those of a more purely commercial character.

It will therefore be well if teachers will exercise some discrimination in recommending candidates to enter. It is very unsatisfactory to all concerned to have to reject such a large proportion of candidates. On the other hand it must be remembered that even to the unsuccessful the examinations may have served a useful purpose as a stimulus to study. They must not therefore allow their failure to be a source of discouragement, but rather regard it as an indication of the weak points by remedying which they may be encouraged to study and to do better another year.

We may now turn to the manner in which the various subjects were dealt with, and the comments upon them of the examiners.

The examiner in Arithmetic thinks that the advantage of the division of the whole examination into three Stages has been confirmed. The inclusion in one list of

those who only desired an Intermediate certificate, and those who were striving to pass the Advanced test, caused the percentage of successes to appear low. Now the intention of the candidates finds its expression in the choice between the second and third Stages, with the result that the percentage of First-class passes in both Stages in higher than before. On the whole, the standard in Arithmetic seems to have risen a little. In the Advanced Stage the candidates seem, in many cases, to have shown a lack of knowledge of the use of logarithms, which is included in the syllabus; and in the Intermediate Stage the common fault occurs of taking a particular case when it is required to prove a general statement, thus affording an illustration, but no proof. The candidates in the Elementary Stage have done better than in any previous year.

In his comments on the English papers, the examiner remarks, with reference to the Advanced Stage, that few candidates obtained a high total of marks, but that, on the whole, the paper was dealt with in a satisfactory manner. The questions on syntax were treated in an intelligent manner, but the section on historical grammar was less satisfactory. Some of the essays were excellent, and though the paraphrasing was in great part superficial, some excellent epitomes were given. The answers on the history of literature showed a fair acquaintance with the titles of books and the names of authors, but not much familiarity with the works themselves. In the Intermediate Stage also some of the essays were extremely good, and so were some of the business letters. The section on grammar was not well answered, but the composition section was better done.

The Book-keeping examinations show the largest increase of any year. The examiner, by means of a table in which he has calculated what this year's results would have been, had the old standards been followed, so as to form a general idea of the relative merits of the candidates between this and the previous years, finds that while there would have been a slight falling off under the old *régime*, the standard of merit has been considerably raised, with a corresponding increase of failures. The answers to the special questions in Stage II., were, upon the whole, poor and disappointing, but the working of the exercises was rather better than usual. There is, however, still plenty of room for improvement in form and neatness, and also in arithmetical accuracy. On the whole, the training of the candidates appears to have been careful and practical; but it is evident that in some of the centres the teaching available leaves much to be desired. This is evident from the fact that the bad papers come in batches apparently from the same centre. The papers in the Advanced Stage showed fair average merit, but a good deal of carelessness in arithmetical work. The First-class generally, and especially those who have obtained the highest places, showed considerable knowledge of the subject.

In the Elementary Stage, the result, as a whole, is not so satisfactory as in the past two years, the percentage of the really good papers is a trifle less, that of really poor papers nearly twice as great as in 1903 and 1904, though better than in 1902; while the medium papers getting from 30 to 69 per cent. marks (20 per cent. above and 29 per cent. below the dividing line)—apart from actually passing or failing, is a little below that of 1903 and 1904.

"It is, perhaps, useful for the most ignorant to get some idea of what an examination means and to get accustomed to its methods, but apart from that consideration, I should say that more than 100 candidates were totally unprepared, and ought not to have entered for the examination. Of course, such tend to swell the percentage of what one might call legitimate failures."

The following are the examiner's remarks on the papers worked in the Advanced Stage of Commercial History and Geography:—

"Some excellent work was received from a few of the candidates, but the proportion of failures was large, nearly 46 per cent. of the total. This is no doubt largely due to the fact that the examination is a new one, and many of the candidates apparently have not realised the standard that must be reached in order to maintain a true distinction between the Intermediate and Advanced Stages. Too many of the answers betrayed an insufficient study of maps, so as to ascertain among other things how physical features influence, and in some cases, control the relations of towns to one another with respect to the means of communication. In answer to the question about the trans-Alpine connections of present and past times, one candidate said the difference between now and the Middle Ages was "that between railway tunnels and mountain passes, and direct railway routes and winding valley roads." A proper study of the map would have shown him just how much, and at the same time how little truth there is in this observation. Many of the candidates gave very indefinite answers to the question on the influence of water power in localising industries, including bleaching and dyeing among the industries under this head. In answer to the question about the mediæval spice trade many wasted time and space in describing

the routes by which the spices were brought to Venice and Genoa, which was not asked. About one-sixth of the candidates added to the value of their answers by really good sketch-maps, but a large number of the sketch-maps were of little or no value as not being illustrative. Sketch-maps which give no additional precision or clearness to answers but merely vaguely repeat what is already stated in the text earn no marks."

As to the Intermediate Stage, he says:—

"As this is the first year in which the higher examination was divided into two, no comparison can be made with last year as regards the number of candidates, but as the new Intermediate Examination is in a large measure on the same lines as the higher grade examination of last year, a comparison may be made with respect to the features of the candidates' work. The amount of attention given to the general questions in the paper may again be noted with satisfaction, and, on the other hand, it has again to be recorded that the questions relating to commercial history were those to which the answers were generally less satisfactory. Little was known of the history of the British trade in raw cotton, or of the commercial history of Antwerp, Bremen, and Rotterdam, and the relation of that history to changes in geographical conditions. The question as to Venice and Genoa, however, was much better answered. The question most avoided, and most inadequately answered when attempted, was that on the German coal trade. This is significant. It betrays a deficiency in geographical analysis. One aim in setting a special subject including only parts of certain countries, was to show the necessity for such analysis. The answers, not merely to that question but also to others, made it plain that the candidates thought of each country as carrying on trade with other countries; as if they were all separate units, not realising the fact that the external trade of different countries is merely the aggregate result of a great number of individual and local needs. If a German manufacturer wants coal, and knows he can get what he wants most cheaply just across the border, it does not occur to him to consider that remote parts of Germany may be remarkably well supplied with coal; and similarly, a German coal-master does not seek to supply distant German customers when he can find more profitable customers nearer at hand, or more accessible if not nearer, though on the other side of a frontier. Among other prevalent misconceptions, may be noted the idea that trade is of little or no account unless it is external, above all export trade; that coal and iron ore are generally found together; and a most exaggerated conception of the importance of inland waterways. The navigability of the Thames to Lechlade was again and again referred to as a matter of importance in relation to the leading features of the trade of London. It was disappointing to find, again and again, in papers of this stage, places stated to be in a 'good position' for trade. Candidates ought to understand that such statements are of no value. What is required in such cases is a statement of the geographical circumstances, that is, the local conditions and place relations, that make a position 'good' for trade. The majority of candidates furnished no sketch-maps, good or bad, and thereby lost marks."

With regard to the Elementary Stage, he says:—

"The number of candidates this year showed a decline of more than 30 per cent. on the number of last year, but the standard of preparation was for the most part much more satisfactory. The candidates fell naturally into groups, in some of which the state of preparation left little to be desired, while in others it was quite the reverse. In more than one of the better groups the chief defect that remained to be remedied was the lack of the power of broad geographical description. In those groups the most defective answers were those to the first question, which asked primarily for a description illustrated by a sketch-map of one out of three counties, each of which has well-marked distinctive features, and secondarily for some particulars with regard to the chief town of the county described. The following may be taken as a typical answer from one of the groups referred to, an answer, it should be mentioned, taken from a paper which was on the whole a very good one, indicating decided intelligence:—'Aberdeen manufactures woollen goods, carpets, machinery of many kinds, notepaper and envelopes, chemicals, and has the largest comb factory in the world.' Now, even if all that is true, these burdensome details are uninstructive, uneducational, and non-geographical, and the enumeration of them does not make up for the entire absence of description, for the omission of any mention or indication of the Grampians, and for the defects of a sketch-map which showed nothing but an indifferent outline and the direction of the Dee. Such answers indicate too great dependence on text-books and books of reference. The remedy is to cultivate the habit of learning as much geography as possible directly from the map, and setting forth what is learnt in significant sketch-maps, however rough these may be."

As to Shorthand, the examiner considers that the work on the whole was good, though many candidates failed to obtain the Advanced standard who might have successfully tried for the Intermediate. As to the Intermediate Stage he says:—

"A month or two devoted to speed practice should enable most of those who failed in this stage to take a high place in the next examination, the failures being due less to want of acquaintance with the system than to lack of training in writing quickly from dictation. Many students over-estimate their attainments, as far as speed of writing goes, or are

prematurely sent up for examination by their teachers in the hope that they may struggle through and add another pass to the credit of the school. 'Hasten slowly' is a golden rule for the shorthand student."

As regards the Elementary Stage, looking upon it entirely as an elementary test for students who have not finished their studies, he considers that the general result is highly satisfactory.

The examiner in Typewriting says:—

"I have never examined a better set of papers than those of the candidates who submitted themselves for the senior test. The explanation of this excellent result is to be found in the fact that numerous holders of the Society's medals and First-class certificates awarded for Typewriting in previous years under the late examination scheme came forward as contestants for the more valuable medals, prizes, and certificates offered in the new Senior Stage. The majority of the papers bore unmistakeable evidences of sound and careful training supplemented by actual business experience. The number of failures is attributable not so much to lack of knowledge as to incapacity to write beyond a very low speed—a senior candidate should be capable of operating at an average speed of 40 words per minute."

As to the Intermediate Stage, he says:—

"The quality of the work submitted may be considered satisfactory, but not so the quantity. Until more adequate facilities are afforded students for practice in the acquirement of manipulative dexterity, no substantial increase in the First-class passes can be looked for. An average speed of 30 words per minute is expected in this stage. I advise that more attention be given to the drafting of simple, clear, and concise answers to theoretical questions dealing with typewriting and office work allied thereto, and those appliances employed as auxiliaries to the writing machine. Such training might form matter for home study, and certainly would prove of real value, especially if the students' exercises are carefully scrutinised and the weak points noted and made material for further study. The answers to the theory questions submitted by too many candidates give evidence of want of training in thinking, the *sine quâ non* of successful teaching. Attention is also directed to the fact that candidates were in many instances hampered with defective machines, or machines fitted with exhausted ribbons or pads."

In both cases many candidates showed a good deal of carelessness, and the examiner quotes a number of blunders, which, though many of them are amusing, show a sad lack of common sense on the part of the candidates. As to the Elementary Stage he thinks:—

"The introduction of the Theory Paper, and the more searching test imposed, has led to a perceptible decrease in the number of passes. This year's figures, however, compare favourably with those of 1903. Now that the character of the test is common knowledge, an improvement may be anticipated next year. There are indications that typewriting class-rooms will be better equipped than heretofore, more particularly in reference to appliances for imparting instruction in office procedure as allied to typewriting. I recommend that more time be devoted to reading from manuscripts, and that students be trained to observe also that theory questions covering the examination syllabus be given as home study. Such a method of procedure is the only way of preventing a repetition of such ignorance as was displayed in the answers to the questions given this year."

In Economics the examiner reports that the number of candidates in the Advanced and Intermediate Stages showed a slight increase on the number in the one grade in the previous year. In the Advanced Stage the general level of work was good; in the Intermediate it was not so satisfactory. Candidates would do well to consider carefully the meaning of each question before they attempt to answer it; otherwise their answers are apt to be entirely off the point. More attention needs to be paid to economic history.

The examiner in Précis-writing thinks that the large proportion of failures is chiefly due to many candidates having entered for the Advanced Stage who would probably have been better advised if they had entered for the Intermediate Stage. The work done by the candidates who obtain First-class certificates on this occasion was very good.

In the Intermediate Stage he remarks that indifferent handwriting and want of neatness contributed to many of the failures, but most of them seem to be principally due to lack of experience and inability to grasp the relative importance of statements.

The examiner in Commercial Law considers that:—

"The quality of the papers was, as might be expected, extremely uneven; while some of the best papers were altogether creditable to their authors, there were, at the other end of the scale, papers exhibiting defects which ought not to be found in the work of candidates in a legal subject: such as atrocious misspelling, *e.g.*, 'Gazzit' for 'Gazette,' and in many cases minor inaccuracies in spelling which reflect no credit on the care of the candidate for accuracy; mistranslations of the maxim, *caveat emptor*, were rife, *e.g.*, 'Let the buyer be aware,' and 'No one can give that which he has not got,' which showed that the candidate had not seriously considered the meaning at all.

"Where there is no Third-class there must usually be some failures, but, taken as a whole, the papers

reached a fair average; although there is frequently a considerable disparity between those who just scraped through and those who just failed to get a First-class; this is inevitable."

In Accounting and Banking the examiner notes that as this is the first year of examination in this subject, there can, of course, be no comparison with previous records. On the whole, the knowledge shown by the candidates was fair, and, though 61 failed to obtain a place there were few utterly bad papers, while many of the papers placed in the First-class (though the percentage of First-class is small) evidenced considerable knowledge and ability.

Coming now to the modern language subjects, the French examiner says that in the Advanced Stage:—

"The general results were good. Several sets of answers were remarkably well done throughout. Though an extensive knowledge of commercial French was shown by a fair proportion of the candidates, this part of the work was not so good in general as might be desired. Many of the essays written by students aiming at a First-class certificate were sensible, and expressed in good French; few could be deemed weak. The number of ill-prepared students was rather large. Many of those who presented themselves for examination in this Stage, should have entered for the Intermediate Stage."

Of the Intermediate Stage, he remarks that:—

"The work on the whole was highly satisfactory. In many instances, the exercises were of an exceptionally high order of merit. The translation from French into English was generally good, and that from English into French fairly so. A good knowledge of commercial French was shown by a considerable proportion of the candidates. As a rule, the grammatical questions were well handled, but rather too many defective answers were given to the questions on adjectives and verbs. The number of rejections was not very large, and that of absolute failures was small."

The paper in the Elementary Stage was, as before remarked, a little easier than that of last year, and the number of failures was consequently less.

"The translation from French into English was generally good; though that from English into French was not equally commendable. In dealing with the commercial letters, too many candidates gave literal renderings. More attention to commercial phraseology is desirable. In most cases the grammatical questions were well answered, but the question on the use of pronouns did not often receive adequate treatment. The idiomatic and commercial phrases were very well translated by a few candidates, but this portion of the work left much to be desired. The general results were good, and indicated careful teaching and intelligent study."

The examiner in German remarks on the Advanced Stage that—

"The papers were very unequal in quality. The best were really brilliant efforts, but a large proportion, even of the better papers, contained mistakes in elementary grammar rules, such as inversion, government of cases by prepositions, &c. Many candidates read the questions carelessly, and so made mistakes which they might easily have avoided. At least ten of the candidates showed more courage than discretion in attempting an Advanced paper. On the other hand eight candidates obtained over 90 per cent. of the marks. More attention should be paid to style, both in English and in German. Expressions like 'did not ought' were abundant, and split infinitives enjoyed an enviable popularity. Some candidates have original views on spelling and punctuation."

In the Intermediate Stage, he says that—

"The papers on the whole were satisfactory. Few rose above mediocrity, but only a small percentage were quite devoid of merit. The translation into German was the chief stumbling block. Ignorance of particular words is a small matter, but ignorance of the use of cases and the conjugation of verbs is a bar to success in any examination, however elementary. It must be remembered that without grammar it is impossible to write German or any other kind of prose. Candidates who coin forms like *liebtest*, *müsst*, &c., who are unaware that datives plural end in —*n*, and who show no respect for the three concords, are ill-advised to sit for examination. It is also useful to remember that a translation which is unintelligible cannot be right, and that even Chinamen do not usually journey 'by *boot* on a canal,' or receive Europeans 'yapping with outstretched mouths.' Much carelessness was shown in the transcription of words: Veitel Itzig appeared some scores of times as Beitel Issig, and Shanghai and Macao underwent strange metamorphoses. The same superficiality accounts for some curious renderings of *Missionare* and *Assecurateur*, who are repeatedly identified with millionaires and monkey-owners. Similarly, a confusion of *Binnen* and *Bienen* makes *Binnenhandel* into apiaries. It is not necessary, as some candidates have done, to write the English translation in German script. The effect is more quaint than pleasing."

Of the Elementary, he remarks that:—

"The translation both into German and into English was, on the whole, intelligently done. But there was a striking weakness in grammar, due, perhaps, to excessive devotion to conversational methods. Some candidates seemed to be unacquainted with the terminology of grammar, or they could hardly have confused declension with comparison, propositions with conjunctions, simple with compound tenses. If the principles of word formation

were better understood, many candidates who failed in translation might have recognised familiar roots under a thin disguise: a small vocabulary, judiciously used, will go a long way. Some failures were probably due less to sheer ignorance than to inability to make use of knowledge actually possessed. There were some excellent specimens of German script."

In Italian, on the whole, the greater number of papers showed a thorough study of the subject, and many candidates in the Advanced Stage showed a good knowledge of commercial language.

In Spanish, the examination was satisfactory, and here again the majority of the candidates on the Advanced Stage showed a good knowledge of commercial technicalities.

The Portuguese examiner was generally well satisfied with the work, and thought that the Advanced candidates were well up to the standard.

In Russian and Danish the number of candidates were very few, but the work on the whole showed promise.

In Hindustani no candidates entered for the Advanced Stage. As to those who entered for the Intermediate Stage, the examiner remarks:—

"Candidates must not rely solely upon an ordinary colloquial knowledge of Hindustani, but should endeavour to become more thoroughly acquainted with the language by carefully studying its grammar, and by learning to write the native characters with ease and accuracy. They should also acquire a knowledge of idiomatic phrases, and of the more polished style of composition; and, for this purpose, they should read some of the text-books usually prescribed for examinations at home and abroad."

In Japanese also, there were no candidates in the Advanced Stage, and though the paper was of set purpose made extremely easy, the work of the candidates was not very satisfactory. It is evident that the students had not learned the Japanese alphabet (Kana), and the examiner remarks that to master the Japanese language it is essential for the students to learn it by the Kana, which consists of only 46 phonetic signs. If any one learns the Japanese by Roman character, he will never acquire the real pronunciation, as all foreigners have a tendency to read and to pronounce it according to the phonetic spelling of their own language.

The results in Handwriting and Correspondence (Stage I.) were the best since the examination was started in 1901, and compare favourably with last year's results.

Theory of Music.

These examinations are divided into two subjects, Rudiments of Music, and Harmony. In the former subject, an Elementary and a Higher certificate is given; in the latter, there is also an Intermediate certificate.

The papers were as usual sent out with those for the Intermediate Grade of the Commercial Knowledge examinations, and the examinations were conducted under precisely the same conditions.

The examiner reports that for the Elementary certificate in Rudiments of Music, there were 225 papers; 173 passed and 52 failed. Nine papers gained full marks, and 99 gained at least 90 per cent. of the maximum number. The failures were owing mainly to want of knowledge of intervals, and of how to transpose.

For the Higher certificate, there were 150 papers; 121 passed and 29 failed. Five gained full marks, and 56 gained at least 90 per cent. of the maximum. On the whole the result was very satisfactory. The weakest points were in the analysis of keys, transposition, and the transcription of twelve-eight to four-four time.

For the Elementary certificate in Harmony, of the 64 papers received 53 passed, 11 failed, 7 gained full marks, and 34 gained 90 per cent. or over. The ungrammatical part writing in the "filling-in" exercises was the chief cause of failure.

Of the 51 papers received for the Intermediate certificates 35 passed, 16 failed, none gained full marks, and 6 gained 90 per cent. or over. It seems that this recently established grade is likely to be a useful stepping stone to the Higher certificate. Weakness was sometimes displayed in the harmonization of the cadential phrases submitted. Students at this stage should learn by heart the common approaches to well known cadences such as those given in the question.

Of the 50 papers received for the Higher certificate 34 passed, 16 failed, none gained full marks, and 13 gained 90 per cent. or over. Almost all the failures were owing to the ineptness of the harmonization of the melodies given. It is safe to say that some candidates would be much shocked on hearing the "harmony" they wrote. Really good harmony

cannot be devised unless the mind can conceive the effect of what is written. Ear training in chords and harmonic progression is the only rational path to success.

Practice of Music.

The practical examinations in Music were held this year from June 19 to July 5, eleven days in all.

In all, 437 candidates entered, and of these 418 were examined, a decrease of 138 as compared with last year. There were 319 passes and 99 failures.

The following were the subjects taken up :—Piano, singing, violin, violoncello, viola, and clarinet. 343 entered for the piano, 257 of whom passed; 55 entered for the violin, of whom 47 passed; 3 entered for the violoncello, all of whom passed; 14 entered for singing, of whom 9 passed; 2 entered and passed for the viola, and one for the clarinet. No medals were awarded.

The examiners reported that the chief causes of failure to secure a certificate were owing to the non-observance of good touch and tone, exaggerated accent, or inability to perform the music at the recognised pace. There were also some cases where the candidate showed inadequate knowledge of the minor scales, whilst others were quite unprepared with them. In several respects, indeed, there was evidence of want of care in reading the printed conditions.

Viva Voce Examinations in Modern Languages.

During the present year 23 examinations have been held in London, Manchester, and Bristol.

At these examinations, 681 candidates presented themselves, of whom 502 passed (83 with distinction) and 179 failed. The languages taken up were French, German, Spanish, Portuguese and Italian. The last named language was added this year to the list.

The results of previous years are as follows :—

Year.	Number Examined.	Passed.	Failed.
1902	280	202	78
1903	456	324	132
1904	540	375	165

The following is a complete list of the *Vivâ Voce* Examinations held during 1905 :—

The following are the examiners' reports for French, German, and Spanish :—

French.—"502 candidates were examined. Of these 44 passed with distinction, 333 passed, and 125 failed. The number of candidates examined was larger than in any previous year. In reading, the improvement was particularly marked; in very few cases did the candidates read badly. In nearly every

centre there were some dictation exercises which were practically faultless and a few were perfect. In several cases, however, candidates who conversed with tolerable fluency did not send up good exercises in dictation. The mark of distinction was earned by a fair proportion of the candidates, and the majority conversed readily and sensibly on topics of general interest. The students exhibited much keenness and enthusiasm. The general results were good and tended to show that the training had been sound and thorough."

German.—"133 candidates were examined. Of these 30 passed with distinction, 62 passed, and 41 failed. The results of the examinations show an all-round improvement on those of last year. A larger number of candidates was examined, and the percentage both of passes and distinctions was considerably higher. The dictations were on the whole much better than in previous years, yet there were still a few cases of candidates with a good knowledge of the language and considerable power of expression who were unable to write a passage of German without making many elementary mistakes in orthography. Yet taken altogether the results were very good, and testified to the thoroughly efficient and practical nature of the German teaching in the institutions concerned, while forming at the same time another refutation of the once-held theory of English inability to learn to speak foreign languages."

Spanish.—"I am pleased to be able to report very favourably on the result of the Spanish *vivâ-voce* examination. The reading of a Spanish passage was generally satisfactory. Several exercises in dictation were fautless. The great majority of the candidates understood fluent speech and could express themselves fluently and correctly on the various topics discussed. Out of the 37 candidates who presented themselves for the examination 25 have passed, 7 with distinction; the conversational knowledge of the latter was remarkably good. On the whole the result of the examinations is most encouraging."

EXAMINATIONS, 1906.

With regard to the Examinations for 1906, very little change in the Programme is proposed. The only alteration of any importance is in Shorthand. Formerly all the different stages of Shorthand were taken on the same evening. The different stages will now be taken on two evenings: Advanced (First-class 150, Second-class 120 words per minute), and Elementary (50 words) on one evening; Intermediate (First-class 100, Second-class 80 words) on another.

The alterations originally proposed have been considerably modified in view of the opinions expressed by the various local Committees, and their executive officials, to whom they were submitted. It is hoped that the system now adopted may meet the requirements of the majority of the candidates.

Swedish has been added to the list of subjects in the Advanced and Intermediate Stages, and the examination in Danish will in future be in Danish and Norwegian.

All the other subjects will be the same as last year. It may be hoped that a larger number of candidates may be attracted to the subjects of Japanese and Hindustani, and perhaps some may be induced to enter for Chinese, a subject which has been in the Programme for a good many years without attracting any entries.

It may be well to point out that though the classification of the Examinations was modified last year, its character remain unaltered. The papers now set are of the same character as those of the previous years, which will therefore, as hitherto, form a useful guide to the nature and scope of the Examinations.

INDIAN RAILWAYS IN 1904.*

This annual report contains information of general interest to the community, in addition to its minutely detailed returns of the nature of the traffic carried by, and items of expenditure incurred on, various Indian railway systems. Some interesting particulars are afforded respecting the Indian coal industry during 1904, when the total output from the collieries in India and Burma amounted to 8·23 million tons against 7·44 million tons in 1903. The exports of Indian coal to Indian ports, principally Calcutta to Bombay, Karachi, and Madras, rose from 1·24 million tons to 1·45 million tons, or by 210,000 tons, and those to ports outside India including Burma from 273·87 thousand tons to 896·81 thousand tons, or by 173·01 thousand tons, principally to Rangoon and Ceylon. The imports of coal from the United Kingdom rose from 133·71 thousand tons to 174·71 thousand tons, or by 41,000 tons, and those from other countries, from 30·43 thousand tons to 79·17 thousand tons, or by 48·74 thousand tons. This was probably due to the fall in value of coal in England and low freights.

The total quantity of Indian coal consumed by railways during the year 1904 increased, from 2·20 million tons to 2·45 million tons, or by 250,000 tons, while the amount of foreign coal consumed fell from 17·70 thousand tons to 17·43 thousand tons. The improvement in the traffic in coal carried by railways was due principally to the increase of 604·49 thousand tons and Rs. 20·34 lakhs recorded by the East Indian Railway, owing to larger despatches from colliery stations for foreign railways and for export. On the Bengal-Nagpur Railway the quantity

* Administration Report on the Railways in India. (Cd. 2619.) Wyman and Sons, Fetter-lane, E.C. Price 3s.

carried increased by 106·25 thousand tons, but the earnings were less by Rs. 1·12 lakhs.

Except in regard to cotton, the crops of which were adversely affected by unseasonable rains, there were general increases in the amount of agricultural produce carried. There was a large increase of 1·18 million tons and Rs. 123·77 lakhs in the wheat traffic included under "grain and pulse," which is chiefly attributed to good crops and to an increase in the export demand. A brisk export trade in linseed and rape and mustard seeds increased the traffic under "oil-seeds" by 165,000 tons and Rs. 16·62 lakhs. Under "grain and pulse," rice in the husk also showed an increase of 225,000 tons and Rs. 11·32 lakhs, consequent on a bumper harvest in Burma and a brisk movement of the commodity to Bombay.

From the broad standpoint of financial success, the result of the working of State and Guaranteed railways for the year 1904 was a net gain to the State of 263·22 lakhs of rupees, the largest yet obtained in any year, after meeting, in addition to the expenses of working, all charges for interest on capital outlay by the State and on capital raised by companies, and also the annuity payments for railways purchased by the State, including both interest and the portion that represents redemption of capital. This is the fifth year in succession in which there has been a surplus. After excluding the portion of the annuity, payments representing redemption of capital, Rs. 95·02 lakhs, the surplus to the State for the year 1904 amounts to Rs. 358·24 lakhs. It is to be noted that even this understates the real surplus derived from the railways open to traffic, as the interest charges include the interest on outlay on lines under construction, which, if these lines were being constructed by private enterprise, would be charged to the capital account.

The remainder of the report is mainly technical in its contents, and it well maintains the repute earned by Indian Government statistics for their plentitude of detail and laboured accuracy.

AUSTRALIAN MARKET GARDENING.*

There is an extensive field in the Commonwealth for systematic market gardening, as conducted in Europe and America. In many places the bulk of the vegetable supply is in the hands of Chinese growers, who adopt intense methods of cultivation, too often sacrificing quality to quantity. Although singularly patient and industrious, the Chinese generally adhere to somewhat primititive modes of raising their crops, rarely producing vegetables equal in size or flavour to those exhibited by white settlers at provincial agricultural shows. Many of these exhibits would have a fair chance of securing prizes in the United Kingdom, but the inducements afforded by cereal cultivation prevent settlers from giving much attention to other crops, however promising. With the progress of railway and tramway extension, the opportunities at the command of the market gardener naturally become increased, and by the adoption of improved methods of production, his labours should prove sufficiently remunerative. There are at present few statistical details of the industry, but it has been estimated that in the Commonwealth there are between 34,000 and 35,000 acres under crop, the annual value of the production being about £820,000. Every known kind of European vegetable can be easily raised in some part or other of Australia. Cabbages, cauliflowers, celery, beans, peas, water cress, radishes, &c., are plentiful in metropolitan and suburban markets, but the supply is seldom in excess of the demand. Almost every description of edible root thrives in suitable localities, and amongst other minor crops may be mentioned turnips, mangold wurzel, onions, arrowroot, carrots, parsnips, chicory, and beetroot. Turnips and onions often produce heavy crops, 1,613 tons of turnips having been obtained from 316 acres, and 400 tons of onions from 192 acres. The latter are mostly of the ordinary kinds, the Spanish varieties being somewhat sparingly grown. Leeks and spring onions find a ready market. Mangold wurzel has given 252 tons from 35 acres, while 89 acres under chicory have given 3,578 cwt. Sugar beet, the cultivation of which in Europe has assumed such enormous proportions, thrives remarkably well in many places, but its cultivation for other than agricultural purposes remains limited, although its value for the production of sugar has been fully recognised, the Victorian State Government having expended upwards of £100,000 in an endeavour to develop the beetroot sugar industry. Australian beetroot has furnished, so far as analytic tests are concerned, results superior to those obtained in any other part of the world. Passing to market gardening proper, it may be mentioned that peas and beans are grown for hard fodder for horses, as well as for table use. The peas are gathered when perfectly dry, and are also used for fattening pigs. Those intended for the table include all the best-known varieties. The same may be said of French, broad, and other beans. Cucumbers of superior quality are easily grown, as are pumpkins and melons, which, as a rule, are exceedingly prolific and make excellent jams. In the country districts they are largely utilised as food for cattle and pigs, the spaces between rows of vines or fruit trees in vineyards and orchards being used for their cultivation. Potatoes are grown in all the States. In 1903 there were 116,112 acres under crop, the production being 449,383 tons. In 1904, 88,967 cwt. of Australian-grown potatoes were exported to oversea countries from the Commonwealth, mostly from Victoria and Tasmania. Systematic cultivation on an extensive scale would enable the local markets to become more efficiently supplied, and a valuable export trade in vegetables, both fresh and preserved, to be built up.

* Communicated by Mr. John Plummer, of Sydney, New South Wales.

HOME INDUSTRIES.

Incandescent Gas.—Thirty years ago it was not thought that the London Argand, giving a density of 3·2 candles illuminating power per cubic foot of ordinary 16-candle gas, would be surpassed in its power of developing light from the combustion of coal gas, and as a burner capable of universal adoption, yet a quarter of a century later the Welsbach mantle was giving a light of 80 candles. Of recent years it has been taken for granted that the complete substitution of electricity for gas in the lighting of streets and dwelling-houses was only a question of time, and when the Court of Common Council decided some time ago to substitute gas for electricity for the lighting of certain portions of the City of London the announcement was received with surprise. But the experiment was very successful, and now the Council have returned to gas lighting in Queen Victoria-street, Queen-street, Lower Thames-street, Monument-street, and Fleet-street. In Fleet-street the Gas Light and Coke Company have charge of the new installation, and it is claimed that the street is better lighted at a cost at the rate of £207 per annum than it was by the electric arc lamps which cost £312 a year. And the experience of the other streets named above is said to be similar, a better light being given at something like 22 per cent. less cost. In lighting one of the great objects to be attained is uniformity of illumination, and the avoidance of harsh shadows; and although the gas lamps are not so powerful as the electric arcs, they are more numerous, and, therefore, give a more evenly distributed illumination, with absence of heavy shadows. The light, too, as given from gas burned in incandescent mantles on the high pressure system, has a greater penetrative power in a fog, a very important consideration in cities with the fog capacity of London. The struggle between incandescent gas and electricity for the purposes of lighting involves huge interests. At present it would seem that gas has the advantage, at any rate so far as outdoor lighting is concerned, both in respect to cheapness and penetrative power, but in connection with domestic lighting it has to be remembered that gas lighting injures home decoration, furniture, &c., more than electricity, and matches have to be used.

Dairy Machinery.—A striking point in connection with the Dairy Show just closed was the indication of a growing desire for cleanliness in the transmission of milk from the cow to the consumer. For example, one exhibit was that of an improved can for the carriage of milk from the farm to the shop. It has no seams, is completely smooth on the inside, and has rounded corners, so that there are no crevices, as with the older patterns, for dirt and bacilli to collect in, and it is very easy to clean. In another exhibit by another firm the same principle is applied to the milk and cream cans used by dairymen for the supply of their customers. Here, too, the object is to avoid any receptacles for dirt by putting the milk into a vessel stamped in one piece. For some time past a milk company doing business in the west of London has used glass bottles for this purposes, but the breakage is so great that bottles could never be generally used. And so in other directions, with churns, cream separators, and the like, invention is aiming at what may be called the better avoidance of dirt by means of improved machinery. It is to be noted that Ireland, which not long ago was so much behind the rest of the United Kingdom in the adoption of improved methods of manufacture, is now well to the front. The improvement in Irish methods during the last ten years has been quite exceptional, improvement in manufacture, packing, &c. This is largely, if not entirely, due to the educational efforts of the Irish Agricultural Department, directed by Sir Horace Plunkett, and the growth of co-operation in the form of creameries. English farmers still lag in the rear. They should study Danish and other Continental practice if they would know what co-operation can do.

Cotton Production.—Mr. Egerton, the Governor of Lagos, and Commissioner of Southern Nigeria, speaking in Liverpool last week, told the Chamber of Commerce of that city that in his opinion the British Cotton Growing Association made a mistake at the outset in trying to cultivate cotton themselves on a large scale in West Africa. They could not hope to grow cotton on the sea coast. It is necessary to get to the drier climate of the interior before it can be grown successfully, and there the native should be encouraged to grow cotton, and taught how to grow it successfully. Mr. Egerton's opinion as to cotton prospects on the West Coast of Africa is fully borne out by a report just presented to the Department of Commerce and Labour of the United States. According to this report, in Sierra Leone the Association tried American seeds, but the plantation was not a success. Under favourable conditions Sierra Leone might produce 140,000 bales, but for the next ten years it is not expected that this colony will export more than 6,000 a year. Northern Nigeria, with a population of 20,000,000, and a soil, much of it, admirably suited to the cultivation of cotton, is doing nothing in the way of cotton growing. Lagos, Southern Nigeria, the Gold Coast, Sierra Leone, and Gambia, are capable, says the report, of producing 350,000 bales, but for the next eight years not more than 100,000 can be expected between them. Lack of transportation facilities, and labourers, are the rocks ahead of the cotton cultivation on the West Coast of Africa as in so many other parts of the world. The need for better railway facilities is fully appreciated by both the Imperial and local Governments, which are doing all that it is possible to do, having regard to the limited revenues of the colonies concerned, to supply them. Lagos has already 125 miles of railway, and 70 miles of extension have been sanctioned.

A Hint to Inventors.—The attention of inventors may be usefully directed to the importance of the early patenting of their inventions in Japan, or rather such of them as are concerned with the trade of the Far East. Imitations in Japan of foreign inventions not protected there by patent are not uncommon, Inventions hitherto regarded as having no direct bearing on the trade of the Far East may turn out to have much to do with it, and unless inventors patent their inventions quickly they may find it too late when they become alive to the necessity of patenting. The Japanese Patent Bureau places in its library the official patent gazette of the foreign country containing the description of an original invention, after which such invention is unpatentable, and comes under the clause "publicly known," as covered by article 2 of the Japanese Patent-law.

The Hop Industry.—In a recent reference in the *Journal* to the cultivation of hops, it was said that it is usually in the short cropping years that the losses of other years are made up, and that you cannot lay down any rule that because a crop is a small one therefore it shall be a good or bad one, or because it is a large one, therefore it shall be good or bad. The experience of the present year illustrates this truth. Almost up to the time of gathering the 1905 crop was one of the most promising on record, then came a fortnight of very bad weather, with the result that whilst the total yield of hops is exceptionally large, the quality leaves much to be desired, and it is quality which is the determining factor in relation to profits. "The losses sustained by growers this year" says a report from Canterbury, "are serious, and a large reduction of acreage is certain to take place"; that is to say in a year of the brightest promise almost up to harvest time, the actual result is so disappointing that heavy losses will be incurred. Hop-growing is one of the most speculative of industries, as is shown anew this year.

Wheat Cultivation and Imports.—It is too soon as yet to say whether the remarkable increase in the area under wheat in 1905 will be followed by another increase in the coming cereal year. This increase may be looked for if farmers are persuaded that prices will go higher again, and there would seem to be some ground for the opinion that there will be no sustained fall in prices, notwithstanding present low quotations. The world's wheat crop this year is rather larger than it was last year, but much more than the entire excess is accounted for by the United States and Canada, yet the shipments from those countries, taking the first eleven weeks of the present cereal year, show a decrease of 30·6 per cent. from a year ago, whilst other countries shipped 25 per cent. more. Taking the thirteen weeks of last year ended September 14, the exports from the United States and Canada amounted to 15,396,117 bushels, and from all other countries to 69,078,000 bushels; the figures this year for the same period are respectively 11,783,373 and 87,152,000. We are at the present time drawing our main wheat supplies from four countries, British India, Russia, the Argentine, and the United States. Last year British India sent us nearly six million quarters, and it is hardly likely that quantity will be much exceeded, if it is equalled, this year. The imports from Russia may be expected to be less, and if the imports from the United States continue to shrink, Argentina, and the other wheat exporting centres are not likely to make up the deficiency.

Insurance Business and Inspection.—The insurance scandals disclosed before the Fricke Committee can hardly fail to add materially to British insurance business in the United States, and to diminish proportionately American insurance in the United Kingdom. Four American societies have done an immense insurance business in this country. Not long ago one of them, the least important, but doing a very large business, fell into disfavour for reasons that were shown to be adequate; this was followed by sharp American criticism of a second of the societies, which must have been prejudicial to its English business, and now three of the four are more or less concerned in the discreditable disclosures made to the Committee. And yet official inspection of insurance companies affairs is supposed to be much more complete in the United States then in the United Kingdom. Here under the Life Assurance Act, 1870, and its amendments, each company issuing policies must deposit with the Board of Trade every year its revenue account and balance-sheet of the preceding year, and must at fixed intervals cause an investigation of its financial condition to be made by an actuary, and furnish the public, through the Board of Trade, with the detailed results. In the United States the laws enact still more minute, and much prompter report to the Insurance Departments of the States, and every annual statement is required to show the results of an actuarial investigation, so that the fullest information concerning the business in any year, and the condition of each of the companies is made public early in the following year. Nevertheless misappropriations seem to have been committed upon an immense scale, although the solvency of none of the incriminated companies is questioned.

Insurance in Home Offices.—It is noteworthy that hitherto whilst the life assurance business done by the leading American societies in the United Kingdom has been very large, the amount of life assurance done by British offices in the United States has been insignificant. It is different with fire insurance. The fire insurance business of foreign companies in the United States was comparatively small until 1870, but thirty years later the annual collection of premiums by twenty-four British companies amounted to 35,226,610 dols. Whether, on the whole, the British companies have been considerable

gainers by their American business, is questionable. Be that as it may, the recent disclosures of American methods of management must, for a time at least, check the growth of American insurance business in the United Kingdom. The comparative gain should be great to induce people in the United Kingdom to insure in societies over whose management they can have no control whatever.

OBITUARY.

EARL FORTESCUE. — By the death of Lord Fortescue, which took place on the 10th inst., at his seat, Castle Hill, South Molton, the Society loses one of its oldest members, and one who for many years took a very active part in its work. As Viscount Ebrington he joined the Society in the year 1854, and in the same year he became a member of the Council, and its Chairman, in which capacity he delivered the opening Address of the 101st Session of the Society in November, 1854. He remained a Vice-President of the Society until 1857. He presided at several of the meetings, took part in the discussions, and on several occasions contributed to the *Journal*. The ill health brought on by illness contracted in the Crimea, where he went after the war with a view of improving the conditions of the hospitals, led to his giving up much of his active work in connection with the Society, as well as in other departments of public life; but his interest in, and attachment to, the Society never flagged, and he took occasional part in its proceedings, though he never again served on the Council after his retirement in 1857. As late as 1886 he took part in the discussion on Mr. Willis-Bund's paper on "Fisheries." He was born in 1818, and was educated at Harrow, and Trinity, Cambridge. He was elected a Member of Parliament in 1841, and represented Plymouth, Barnstaple, and Marylebone, until his retirement in 1859, in which year he was called to the Upper House in his father's barony of Fortescue. Two years later, in 1861, he succeeded to the earldom. He held several minor political offices, but the condition of his health prevented his taking a more active share in the work of the Government. He was always known as a staunch advocate of education and of sanitary improvement. Commencing life as a Whig, he always remained a persistent advocate of Liberal principles, though he separated himself from his party on the Eastern question of 1878-79. Until the end of his life he remained a Liberal Unionist.

GENERAL NOTES.

ESPARTO GRASS.—In his report on the trade of the Regency of Tunis (No. 3492, Annual Series) Mr. Consul-General Berkeley says that a new company, called La Société Franco-Africaine des Pâtes d'Alfa, has been found to undertake the local manufacture of paper from esparto grass by means of a new process discovered by a French chemist, M. de Montessus. At present, Algeria and Tunisia export annually about 200,000 tons of this grass, which is almost exclusively shipped to the United Kingdom. The new process consists in rendering soluble the gum and resin contained in the grass by means of fermentation produced by bacteria. The grass is then washed in a carbonate solution, so as to separate, intact and free from foreign bodies, the cellular fibres which constitute a paste similar to that used in the United Kingdom for the manufacture of paper. This fermentation process is said to give exactly the same results as the British process, and it is alleged that it will reduce the present manufacturing price by 175 francs per ton. It is not improbable that the company will seek to obtain special advantages for the collection of the esparto grass which they will need.

ARTIFICIAL SILK. — There seems to be a considerable demand for artificial silk for embroidery and trimmings, and several manufactories have been started in Lyons with a view to producing it on a large scale—a factory at Izeiux (Loire) employing the Givet system, which treats cotton cellulose with salts of copper; factories at Feyzin (Rhone) which follow the system of Chardonnet; a factory employing the Valette system; and a factory in the Department of Ardèche for the manufacture of "Viscose," product obtained from the cellulose of wood pulp without nitration. Referring to the progress of the industry, Mr. Consul Liddell (No. 638, Miscellaneous Series) says that time only can show which of these different systems is most successful, but in the meantime it is not unlikely that over-production will take place.

GLEBE LANDS ACT, 1888.—For some years after the passing of this Act the transactions under it were small. The number of cases in which the assistance of the Board of Agriculture was resorted to in connection with the sale of glebe lands in the first ten years after the commencement of the Act averaged 52 per annum only. In the three years 1899-1901 the average number of completed transactions rose to 77 per annum, while in the three years 1902-4 the average was 125, the figures of the past year amounting to no less than 162, covering 2,835 acres, the aggregate purchase-money being £135,658. In 1903, 102 sales, comprising 2,179 acres, were carried out, and the purchase-money paid was £69,905. The amount of the official fees received in respect of the Glebe Lands Act during the financial year 1903-4 was £419 15s. These facts and figures are taken from Major P. G. Craigie's report to the Board of Agriculture and Fisheries (Cd. 2453).

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

RESERVOIR, FOUNTAIN, AND STYLOGRAPHIC PENS.

By James P. Maginnis,
A.M.Inst.C.E., M.Inst.Mech.E.

Lecture I.—Delivered January 23, 1905.

Ancient Writing Implements.

There does not appear to exist, except on the shelves of the Patent Office, any systematic record of what has been done to produce the elegant and perfect writing instrument of to-day, known as the "Fountain Pen."

It is probably to many unknown history, but on the other hand, a large number of persons must be well acquainted with what has been done in the past to perfect the writing implements which have become so familiar to all; for in these days of advancement it would be difficult to find anyone incapable of using a pen.

Many inventors, and some of these of the first rank, have devoted much time and ingenuity to the subject, with the object of producing a reliable instrument.

It will perhaps astonish some of my audience when I refer to early inventions, as there is a general belief that fountain pens are of quite modern date.

The time at my disposal will not permit of a complete reference, but I shall endeavour, by short description, drawings and photographs, to present most of the leading types, more or less in detail, and I have been enabled, to a great extent, to do this by the generous assistance of leading manufacturers in England, the United States, and elsewhere, who have readily placed valuable information at my disposal for the purposes of these lectures.

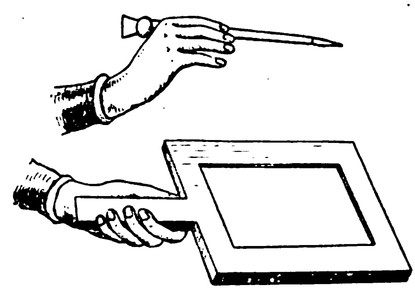
It is necessary to emphasise the fact, that I merely speak as an outsider, a man in the street, from the unbiassed standpoint of one who finds recreation and instruction in endeavouring to ascertain the why and the wherefore of articles of utility. I have, therefore, no axe to grind, unless it be to call the attention of the younger members of my audience to the pleasure to be derived from the occupation of tracing the history of inventions.

To trace the history of fountain pens, is the primary objective I have in view, but I think that a hasty *résumé* describing the growth of writing implements generally from early days, would perhaps make the subject a little less prosaic, and to some extent reduce the result of my research to something more interesting than a mere catalogue of inventions, however instructive such a catalogue might be.

In D'Israeli's "Curiosities of Literature" we read: "When men had not yet discovered the art of recording events by writing, they planted trees, or they erected rude altars, or heaps of stones as remembrances of past events." And again: "Hercules probably could not write when he fixed his famous pillars."

Stylus and Tabula.—As long as people wrote upon tablets covered with wax, they were obliged to use a style or bodkin, made of bone, metal, or some other hard substance. A curious

Fig. 1.



drawing in a fine manuscript, once the property of Charlemagne, and now preserved in the public library of the ancient city of Treves, on the Moselle, furnishes the illustration (Fig. 1) here

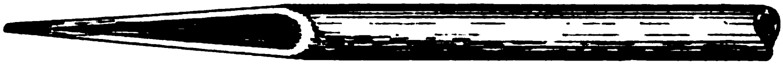
shown of a tabula held by a handle in the left hand of the scribe, exactly resembling the old horn book of our village schools. The surface is covered with wax, to be inscribed by the metal style held in the right hand. These styli were sometimes surmounted by a knob, but frequently were beaten out into a broad flat eraser used to press down and prepare the waxen surface for a new inscription. The stylus here shown illustrates both knob and eraser, or burnisher. (Fig. 2.)

Fig. 2.

Ancient Roman Stylus.

When it became usual to write with coloured liquids, scribes employed a reed, and later, quills or feathers. It is rather astonishing that there is no authentic record as to the precise kind of reeds the ancients used for writing, though writers mention the places where they grew wild, and where it is highly probable they grow still. It is, however, reasonable to suppose that the same reeds are used even at the present time by all the Oriental nations, for it is well known that among the people of the East, old manners and instruments are not easily banished by new modes and new inventions.

Fig. 3.



Reed Pen—as still used in the East.

Reed Pen.—Most authors who have treated on the history of writing have contented themselves with informing us that "a reed was employed," but the genus of grasses called by the ancients "Calamus" and "Arundo" is more numerous in species than the genus of grasses to which their corn belonged. A writer—Chardin—speaks of the reeds which grow in the marshes of Persia, and which are sold and much sought after in the Levant, particularly for writing. Chardin says, "Their writing pens are made of reeds, or small hard canes of the size of the largest swan quills, which they cut and slice in the same manner as we do quills, but they give a much longer nib." These canes or reeds are collected along the Persian Gulf, in a large fen. They are cut in the month of March, and when gathered are tied up in bundles and buried for six months, when they harden and assume a beautiful polish and colour—a mixture of black and yellow. None of these reeds—Chardin says—are collected in any other place. As, he says, they make the best writing pens, they are transported throughout the whole East.

Although the reeds were split and formed to a point like our quills (Fig. 3), it certainly was not possible to make such clean and fine strokes, nor to write so long and so conveniently with them, as one can with quills. The use of them, however, was not entirely abandoned when people began to write with quills, which in every country can be procured from a bird extremely useful in many other respects. Had the ancients been acquainted with the art of employing goose-quills for this purpose, they would undoubtedly have dedicated to Minerva, not the owl, but the goose.

A writer in the fifth century states that Theodoric, King of the Ostrogoths, was so illiterate and stupid that during the ten years of his reign he was not able to learn to write four letters at the bottom of his edicts. For this reason the four necessary letters were cut for him in a plate of gold, and the plate being laid upon paper formed a stencil from which he is said to have traced the characters with a quill.

This account is not improbable, for history tells us that almost about the time of Theodoric the Western Empire was governed by the Emperor Justin, who also could not write, and who used, in a like manner, a piece of wood having letters cut in it, but in tracing them out he caused his hand to be guided by one of his secretaries.

The English word "pen," the French "plume," and the German "feder" all signify the same thing, a "wing feather." There are many traces that quills were used as writing instruments by the ancient Romans. Perhaps the earliest specific allusion to the quill occurs in the writings of St. Isidore, of Seville, early in the seventh century.

For a long time goose quills were solely used, but afterwards the wing feathers of swans, turkeys, peacocks, and crows were requisitioned. The goose quill, described by Byron as—

> Nature's noblest gift,—my greygoose quill!
> Slave of my thoughts, obedient to my will,
> Torn from thy parent bird to form a pen,
> That mighty instrument of little men!

was until 1830 almost the only kind of pen in general use, but it must not be supposed that pens made of various metals did not exist many years previous to 1830.

It is recorded that the Patriarchs of Constantinople, under the Greek Empire, were accustomed to sign their allocutions with tubular pens of silver, similar in shape to the reed pens, which are still used by the Oriental nations. The Chinese and Japanese, however, write with a brush or hair pencil dipped in Indian ink.

Other writers of the seventh century refer to quills in a vague manner, and it is not quite clear whether feathers or reeds are meant. Men of letters, well versed in such matters, assure us, from comparison of manuscripts, that writing reeds were used along with quills in the eighth century, at least in France, and that quills first began to be common in the ninth century.

In convents, it is said, reeds were retained for the writing of texts and initials of manuscripts, whilst for small writing, quills were everywhere employed. This statement must be taken with reserve, as it is probable that scribes and copyists would at first endeavour to write with quills in the same style as had been the custom when using reed pens, in order that the results might not seem very very different from the then usual style. And with quills one can produce writing both coarse and fine. About the year 1433 writing quills were so scarce in Venice, that it was with great difficulty men of letters could procure them.

Inkhorn and Penner.—The scribes of the Middle Ages frequently carried their writing implements appended to their girdles, consisting of an inkpot and a case for pens. The latter was usually formed of leather softened by hot water, and then impressed with ornament, and hardened by baking. This was as strong as horn, of which substance the inkpot, or inkhorn, was generally made.

The drawing shown on the screen is reproduced from an engraved brass to the memory of a notary of the time of Edward VI., placed in a church at Ipswich, representing a penner and ink-horn slung across the man's girdle. It will be seen that they are held together by cords which slip freely through loops at the side of each implement, the knob and tassel at each end preventing them from falling.

Writing Table of a Scribe. — With the invention of the printing press the very laborious process of producing books by handwriting vanished for ever. Imagine the working table of a scribe, contemporary with the invention of the printing press, as depicted in a picture in the gallery of a museum in Naples. The pages upon which he is at work lie upon the sloping desk. In the table beyond he has stuck his penknife. The pens lie on the standish in front of him. Bottles of ink of both red and black colours are also there, and an hour glass is at hand to give him due note of time, not necessarily because he was in any particular hurry, for they seemed to have plenty of time in those days. A pair of scissors and a case for a magnifying glass to assist his sight, are also within easy reach.

Eastern Writing Implements. — Another such picture shows the writing materials and implements as used even to-day in Palestine. The scribes do not carry the genuine inkhorn nowadays, as did the prophets of old, but instead they have an apparatus consisting of a metal or ebony tube for reed pens, with a cup or bulb of the same material attached to the upper end to contain the ink. This tube they thrust through the girdle and carry with them at all times as we carry our pencil or fountain pen, always ready for use.

Brass Reed Tube and Ink Bulb.—I am indebted to my friend Mr. A. Hervé Browning for kindly affording me the opportunity to show you this illustration. Mr. Browning lent me the original from which Fig. 4 has been photographed. It is an actual example of one

of these tubes and inkpots, which was shown on the last slide. It is made of brass, and is richly carved all over its surface. The ink

FIG. 4.

used in it was of a semi-fluid consistency, and in order to prevent its flowing from the ink bulb a piece of sponge was inserted.

Portable Ink Bottle.—Many will remember the general use, not a great many years ago, of a glass bottle so formed as to be safely carried with its neck inserted in the button-hole of a coat, and it will be evident to most that it forms a survival of the inkhorn.

Japanese Writing Box.—Here, in Fig. 5, is an interesting photograph of the writing box as used to-day by the Japanese, at home and in business. In the centre of

FIG. 5.

the box is a slab or palette of stone, formed with a sloping surface, becoming gradually deeper, till a well is formed at the further end. A supply of water is kept in the little bronze vessel seen beyond. When ink is required, a little water is poured on the slab, and Chinese or Indian ink is rubbed upon it till of the right consistency, just as we engineers and architects rub up Indian ink for the preparation of drawings. The writer then fills one of the pens which you see in the box, and which are really brushes, and proceeds to make the wonderful marks which in his language represent words and sentences. The pens are made from the hair of deer, sable or rabbit, fixed in reeds.

I may here say that I am indebted to Captain Sparks, of Duke-street, Manchester-square, for the specimens of Japanese pens, and also to Messrs. Yamanaka, of New Bond-street. who very generously lent me this writing box as well as the following objects.

FIG. 6.

Japanese Pen Tube and Ink Box (Bronze).—Of course the Japanese have their portable writing implements. Fig. 6 shows the kind of thing the milkman, the baker, or the tax collector carries in his sash when he goes on his rounds. It is made of bronze. The tube contains his pen, whilst the beehive-shaped box at the other end of the silken cord contains

ink. It will be seen that the box consists of two compartments, the lower one contains the Indian ink in a sponge, and the upper compartment holds some red endorsing ink with which he charges his business seal with ink, and endorses his little bill or receipt.

Japanese Pen Tube and Ink Box (Ivory).—In Fig. 7 we see a more elaborate form of the same kind of implement, made of ivory. The stem is hollow, and holds the pen. The whole

FIG. 7.

is richly carved, as is also the bowl containing the sponge saturated with ink. It will be noticed that the general outline of this is very similar to that of the reed tube and ink bulb already referred to.

From the stylus of the ancients to the goose quills of our fathers was a great step in advance, but the requirements of advanced civilisation demanded still further strides. The softness of quill pens and the constant trouble required to mend them and keep them in working order naturally led to the search for some more enduring substitute.

Quill Nibs.—In September, 1809, appeared an application from Joseph Bramah (3260) for "a new method of making pens, penmaking machines, &c." This is interesting, as it marks the date when quills were first cut up into several pieces, and as many nibs were formed therefrom. He describes how the quill may be cut longitudinally into three or even four parts, and each of these cut transversely into two, three, four, or even five parts, and a writing point formed at each extremity of these subdivided lengths. He then goes on to describe a machine whereby the quills may thus be treated. I shall have occasion to refer to this specification later.

In October, 1818, Charles Watt (4299) describes a process for gilding and preparing quills and pens by manual labour and chemical operations, so as to render them more durable and useful. He describes the process of cleaning and dipping in a dilute aqueous solution of the nitro-muriate of gold, treated with phosphuretted hydrogen gas; then sulphurous acid gas, until finally, after repeated treatment, a thick coating of gold is deposited.

Quills with Steel Nibs.—In 1852, Myers and others obtained a patent (525) for the making of pens or nibs to be applied to quill holders. The specification also describes the shaping of quills at the end, so that they might be used as ordinary penholders to hold the nibs in general use.

Three years later a somewhat similar arrangement was patented (591) by William Hill.

The specification (7333) of Henry Stephens, of March 1837, refers to certain improvements in pens for writing. He employs quill, horn, or other animal substance of the requisite thickness, which he cuts into proper forms by means of a cutting punch or other instrument. A pair of dies shaped according to the model or required curved or bent form of the pens intended to be made, are heated to a degree sufficient to harden the materials without destroying their texture; the cut pieces or blanks are placed between them, subjected to pressure, and not removed till the dies are quite cold, when the nibs will have become set or fixed in the required form. In order that the slit may not be allowed to pass too high up, the pen is placed under a cutting punch and die, and a small hole is perforated at the place to which the slit is to extend. It is also stated that the curving process may be performed first, and the cutting and shaping afterwards. A penknife may be used to remove any roughness, and also to adjust the points.

Charles Goodyear in 1853 describes a process (1693) for making pens of vulcanised india-rubber, composed of two parts by weight of india-rubber and one part by weight of sulphur. This is rolled out into a thin sheet of the thickness of a strong quill, and then cut up into suitably narrow strips, which are placed between moulds made of glass, one being concave and the other convex, and subjected to heat gradually increased to about 295° to 350° Fahr., and afterwards allowed to cool gradually, when the curved strips are taken from the moulds, cut into lengths, and made into pens.

In the specification (1856) of Henry Peters

in 1853 the inventor states :—"My improvement in pens consists in making them of tortoiseshell, and the other shells called tortoiseshell in commerce."

He presses thin sheets of such shell into a semi-cylindrical form, and from these he cuts the pens and fashions them by any suitable means. He states that pens made of tortoiseshell have all the desirable properties of quill pens and last much longer, and, like the quill, when worn can be mended in the same manner.

In 1859 (68) Edward Cobbold proposed making his pens principally from strips of reed or cane. These he divests, at intervals, of the soft spongy material which lines the interior. The pens are made from the hard outer shell, while the soft part forms a stop to the slit. This would appear to be a retrograde suggestion rather than an improvement.

In 1861 (2112) Evans and Concanen describe how pens may be made from horn in its natural structure, or dissolved and formed into horn sheet by ordinary process. Blanks are stamped or cut out from the sheets, softened by the heat of steam or other means, moulded into pen form, provided with slits, and allowed to resume the natural state of the horn from which they were manufactured.

In the invention of George Leslie in 1861 (2828), the pens are made of hardened caoutchouc, gutta percha, or gum, known as vulcanite or ebonite. The inventor moulds them into the proper shape while the gum is in a plastic state, and hardens them by the ordinary process, or shapes them with files or other tools, after the material has been hardened and become vulcanite or ebonite.

These examples will tend to show that quill pens were not considered perfect as writing implements. They were too troublesome to keep in order, and there was an evident desire to produce something more enduring.

It must not be supposed that I have cited anything like all the attempts that have been made to improve the quill, but I have selected these typical examples as illustrative of my suggestion that something better was required.

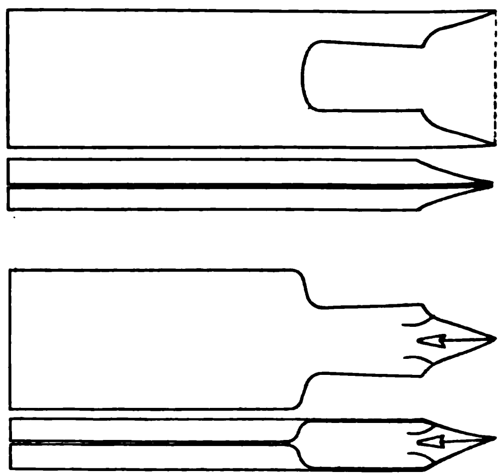
It is recorded that metal pens were used in the fifteenth and sixteenth centuries, and a writer (in 1733) refers to steel pens. The following interesting note appears in a manuscript document in the library of Aix-la-Chapelle, entitled, "Historical Chronicle of Aix-la-Chapelle," second book, year 1748, edited by the writer to the mayoralty, Johann Janssen. He says :—

"Just at the meeting of the Congress I may, without boasting, claim the honour of having invented new pens. It is, perhaps, not an accident that God should have inspired me at the present time with the idea of making steel pens, for all the Envoys here assembled have bought the first that have been made, therewith, as may be hoped, to sign a treaty of peace which, with God's blessing, shall be as permanent as the hard steel with which it is written. Of these pens, as I have invented them, no man hath before seen or heard. If kept clean, and free from rust and ink, they will continue fit for use for many years. Indeed a man may write twenty sheets of paper with one, and the last line would be written as well as the first.

"They are now sent into every country of the world as a rare thing, to Spain, France, and England. Others will no doubt make imitations of my pens, but I am the man who first invented and made them. I have sold a great number of them at home and abroad at 1s. each, and I dispose of them as quickly as I can make them."

Barrel Pens as First Made.—There are many others who lay claim to having made the first steel pens, but the late Sir Josiah Mason has stated that his friend and patron, Mr. Samuel Harrison, a maker of split-rings,

FIG. 8.



such as are used for keys, made a steel pen for Dr. Priestley about the year 1780. He, Harrison, took a sheet of steel, made a tube or barrel of it, the edges meeting to form a slit. He then filed away the edges of the tube in such a manner as to form a rough barrel pen. The illustration (Fig. 8) shows how the pen was fashioned, the slit extending right along the back of the barrel, not merely at the point as in the modern method shown below. The upper drawing in each instance illustrates

the form each pen would assume if flattened out.

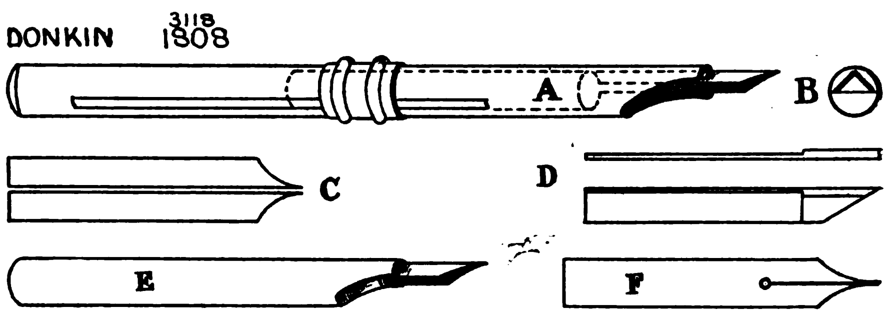
Harrison's method was improved upon by a blacksmith named Fellows, of Sedgeley, Worcestershire, who punched a rough "blank" out of thin sheet steel. He then formed this blank into the barrel shape, and while the metal was soft marked the place where the slit was to be with a sharp chisel. Before tempering, this mark was "tabbered" or gently beaten with a small hammer until it cracked right through, thus forming the slit. Fellows began making pens in 1795, and was able to produce them at from 18s. to 30s. a dozen, whereas Harrison's were 5s. each.

Donkin's Pens.—In 1808 Bryan Donkin applied for and obtained the first patent (3118) for metal pens. He claims a pen upon a new construction, and states that the pen may be duced in Fig. 9, redrawn from his specification.

Specimens of these pens are to be seen in the Educational Department of the South Kensington Museum.

Perry's Pens.—In the patent (5933) of James Perry, of April, 1830, we have an improvement in pens, consisting in producing them from hard, thin, and elastic metal, with the necessary flexibility, and a length of slitted or cleft space scarcely exceeding that of quill pens. The result is effected, first, by a central aperture space or hole of circular, oval, square, or other shape, formed in the pen between the nib and the shoulders, or, secondly, by making between the nib and the shoulders one or more lateral slits on each side of the central slit, and rising out of or branching from it. The pens, the patentee states, should be made of the very best spring steel, and they

FIG. 9.



of any "metal or material fit and proper" for the purpose. It is made of two parts as shown at C "flat or nearly so," having those parts of the flat sides opposed to each other, and forming the slit of the pen, rather thicker towards the points as shown at D, in order, as he says, to prevent the pen from spluttering. They are then put into "a tube or other fit receptacle," "applied to each other in an angular position," as shown at B, and thus constitute a pen.

Another method is to form the pen of one single flat piece, as shown at F, afterwards bent to the proper angle, before inserting it into the tube E. To increase or diminish the elasticity of the pen, the inventor suggests its being placed further out, or within the tube holder A, a slide being provided for this purpose. The patentee states that these nibs may be made of steel, brass, silver, gold, platinum, or any other suitable metal or material. Mr. Donkin's illustrations are repro-

should be of about the same diameter as those made from quills. It has been suggested that Perry got his idea of making steel nibs from having seen the quill nibs of Bramah, and there is probably some foundation for the suggestion. Hitherto, pens had only been made in barrel form in imitation of the reed and the quill, except in the case of Donkin's invention, which does not appear to have found much favour.

With such a variety of nibs as are to-day everywhere obtainable there ought to be no difficulty in finding one to suit every style of writing, from the hair lines of the lithographer, to the broad, bold lines of the German text employed in engrossing legal and other documents. There certainly is no valid excuse for him who can never find a decent pen. And considering the many processes through which the pen of to-day passes before it is considered fit to place before a critical public, it is marvellous that pens can

be bought at prices so low as fourpence a gross, which formerly cost as much as eight shillings a gross.

Perhaps I may now be permitted to give some general idea of the interesting growth of the steel pen of to-day, from the time of the punching out of the "blank" from the strip of very high quality steel from which it is taken.

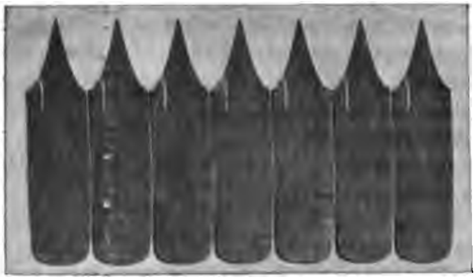
Cutting Out.—The steel of course is in an annealed state, easily manipulated without fracture, and here is a photograph of a group of "blanks" (Fig. 10) as they fall from the die

FIG. 10.

of the fly press, operated by girls, who become very deft and skilful at their work. The punching of the steel is so rapidly and neatly executed as to be done with mathematical precision. It will be found on examination that the intervals between the perforations are perfectly uniform. Having perforated the entire length of the ribbon of steel along one edge, it is quickly reversed, and the other edge is treated in a similar manner.

Side Slitting.—The next operation is that of forming the two side slits (Fig. 10A) which give

FIG. 10A.



elasticity to the nib. I need not now go into details as to how the various processes and operations are carried out, but will pass along from one to the other.

Piercing.—This operation has already been referred to, and the object of the existence of the "pierce" explained. Of course there are many nibs made without a pierce, notably gold ones, but most steel nibs are pierced to give them elasticity, and to increase their ink-holding capacity.

Marking.—Manufacturers who are proud of their productions take a pleasure in stamping their name on the nibs they make, and in order to identify one kind of nib from another, a mark, or a letter, or a name is stamped on the nib to be seen of all men. On the other hand, there are manufacturers so modest, that for a mere consideration, they will stamp some one else's name on the nibs they make. In the illustration, we have the name of Joseph Gillott, whose name is known throughout the civilised world.

Annealing.—The various manipulations having somewhat hardened the steel, it becomes necessary to soften or anneal the blanks previous to further development of the nibs. They are moderately hard, but before they can be made to assume the familiar curved form, it is necessary that they should be considerably softened, so as to be of a more yielding disposition, and to effect this quantities of the immature nibs are placed in iron pots, afterwards carefully covered with charcoal dust, and sealed to prevent the entrance of furnace gases. Thus prepared, the pots are placed in larger pots of the same kind and again covered and sealed, and then placed in a muffle furnace till they become of a dull red heat, when they are taken out and allowed to cool. The blanks have now become soft and pliable, readily taking the various shapes into which pens are formed by stamping and embossing presses.

FIG. 11.

Raising.—There is now no difficulty in making the blanks assume the appearance here shown in Fig. 11 by a process technically known as "raising," but, as the nibs are soft, their constitution having become limp and

enfeebled from the recent annealing process, they must be braced up anew in the hardening tub, for now they have no more elasticity than so many pieces of lead. They look like nibs, and that is all.

Hardening.—Hardening is accomplished by heating the nibs to a dull red, having placed them first in shallow pans, and then, when at the right heat, which is estimated by their colour, they are overturned into a bath of oil, from which they are afterwards removed, having a greasy, black, disreputable appearance, and a temper as brittle as glass. Boiling in a strong solution of soda and water removes the grease and impurities, and the nibs emerge with a white and clear complexion, but they are much too brittle.

Tempering.—They have next to submit to the process of tempering, which is effected by placing a quantity of them in an iron cylinder, capable of being slowly revolved over a fire, or gas jet. Under this treatment, as everyone knows, they change colour with perfect regularity, and as soon as they are seen to assume a dark blue colour they are taken from the fire and allowed to cool.

Cleaning.—The nibs, however, again require to be cleaned to remove the impurities caused by heating and handling. They are therefore put into tumbling barrels, containing water and powdered fireclay, the fragments of crucibles and foundry melting pots, mixed with emery. These barrels are kept revolving for some time, till by abrasion the nibs are at length polished with a surface like silver.

Straight Grinding.—To improve the flexibility of the nibs, they are now ground near the points in a longitudinal direction, equivalent to the scraping of a quill pen with a penknife.

Cross Grinding.—And then they are ground in a transverse direction, a process which gives them a smart appearance.

Messrs. Gillott had an ingenious little machine in their works in Birmingham, which automatically gronnd the nibs, first in one direction and afterwards in the other direction as described, at the rate of about twenty-four in a minute, the pens being fed into the machine at this rate by hand. After grinding, the nib was released and projected with considerable force along a tube, and into a basket placed below. On the occasion of a Royal visit to Messrs. Gillott's works, His Majesty King Edward the Seventh, then Prince of Wales, was much interested in the little machine, and having watched its lifelike movements for some time, caught one of the flying nibs as it emerged from the tube, the result of which was a small puncture of the palm of the Royal hand. This incident gave rise to the naming of the machine, which my guide (who narrated the incident to me when I visited the works) introduced to me as the "Royal Blood Machine."

Slitting.—Perhaps the most important process in the making of a nib, remains to be carried out. It is that of slitting, but time will not permit me to go into the method in detail. Suffice it to say that the slitting is now accomplished, and if properly done, a perfect nib is the result.

Colouring.—In order to improve the appearance of the nib, or as a distinguishing feature, it is now coloured by a gentle heating, which gives it the familiar bronze colour. Or, sometimes the nibs are plated with copper, or gilt, or nickel-plated.

Varnishing.—Finally they are varnished by immersion in a solution of shellac dissolved in spirit, made to adhere to the nibs by gentle warmth. When dry, they are examined carefully, all defective nibs being rejected, weighed into grosses, and carefully packed in neat cardboard boxes, ready to be introduced to the world as an instrument "mightier than the sword." At the present time, there are about thirteen, or more firms engaged in the penmaking trade in Birmingham alone, consuming about 28 tons of steel per week in the production of pens and penholder tips. Besides the British factories, there are some four or five on the Continent, and perhaps only two or three in the United States. In Birmingham alone, the average weekly production equals about 250,000 gross, or 36,000,000 pens, finding employment for some 4,000 women and girls, and about 650 men and boys. In addition to these, about 300 more women and girls are employed in making the neat paper boxes in which the pens are packed. That the industry is an important one there can be no doubt. Messrs. Gillott's works in Birmingham are very extensive, and those of Messrs. Perry and Co. are no less important. Messrs. Brandauer also have a huge factory. Besides these there are other works in Birmingham of equal importance, such as John Mitchell's, Myers and Sons, William Mitchell's, and others whose names are familiar to all.

Many attempts have been made to find a substitute for steel in the manufacture of pens. It is not a great many years since it was almost an impossibility to find an ink that did not rapidly corrode metallic pens, by reason

of the ingredients used in its manufacture. Even to-day we are warned that certain inks are highly corrosive. Several patents were granted to inventors for the application of certain metals, other than steel, to the making of pens, and the following are a few of them, by way of example.

In 1822, Hawkins and Mordan describe certain improvements in pens (4742), consisting in making them of tortoiseshell or horn, and impressing into the wearing parts, when they are softened with hot water, small particles of diamond, ruby, or other very hard substance. And again :—In lapping a small piece of thin sheet gold over the end of a piece of tortoiseshell, and pressing the gold into it whilst in a soft condition. The pen is afterwards formed by cutting away the superfluous gold and tortoiseshell together. And again :—By applying to the nibs of pens of tortoiseshell, horn or quill, small particles of diamond, ruby, or other gem, causing them to adhere by a suitable varnish or cement unaffected by ink.

Scully and Heywood, in 1855 (2084), suggest that, by reason of its non-oxidisable qualities, aluminium may be used in place of brass, copper, and silver, for wind and stringed instruments, and also as a material for pens, penholders, and inkstands. The metal for pens they propose to roll or beat into thin sheets, in order to give rigidity and toughness to it, and then, by ordinary means, the pens may be made from these sheets.

In the invention of Bewicke Blackburn (804) in 1857, each pen is formed of two pieces of glass or porcelain (set in a frame of metal or some other flexible material) composed of two parts, separated from each other in such a manner that the flexibility of the frame will admit of the points of the pen separating or expanding, and contracting when writing.

In the months of February, March, and May, 1863, three distinct groups of inventors (Robert Pinkney 455, Lutwyche and Lutwyche 682, and Page and Wayne 1165) applied for patents for making pens of aluminium bronze, composed of aluminium and copper in varied proportions. This appears to be a peculiar coincidence.

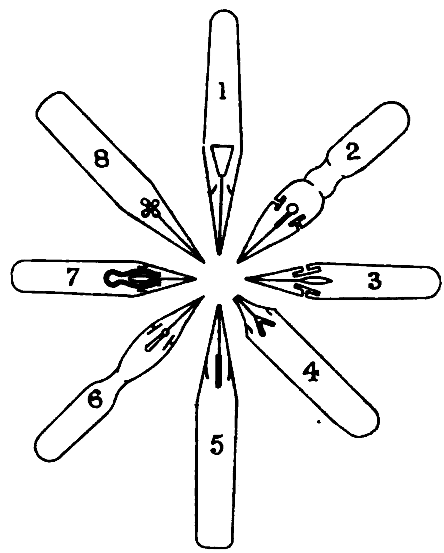
In the invention of Louis (1711), in 1876, the pen is to be of gold, of not less fineness than 16 carats, covered with vulcanised indiarubber, and provided with an iridium tip or point.

These are specimens of the many efforts on record of inventors striving to improve the pen, and one cannot help but admire the ingenuity and skill, as well as the perseverance which such records represent. On the other hand, it was no doubt assumed, that considerable fortunes were to be realised in case of success. Experience has shown that a greater harvest of wealth has over and over again been reaped by the inventors of small articles of general utility, than has fallen to the lot of originators of more pretentious inventions.

Reservoir Pens.

Many attempts have been made to increase the ink-holding capacity of the ordinary writing pen, or nib. As already mentioned,

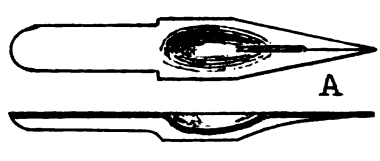
Fig. 12.



one method of attaining this end, was the provision of an orifice or "pierce" as it is technically called, some examples of which are shown in Fig. 12.

Some nibs were provided with deep recesses or pockets as shown in Fig. 13 (A), Fig. 14 (B), Fig. 15 (429, 1883). Another favourite method

Fig. 13.



was that of folding over the sides of the nibs. The nib was stamped out provided with wings, which could be folded, so as to form an ink reservoir under the nib, as in Fig. 16 (C), Fig. 17 (1616, 1890), and Fig. 18 (10984, 1884).

FIG. 14.

FIG. 15.

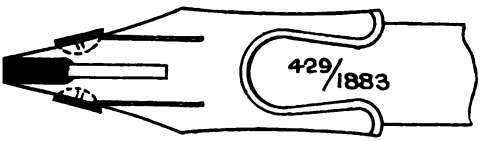


FIG. 16.

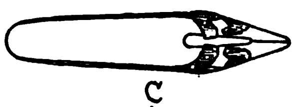

FIG. 17.

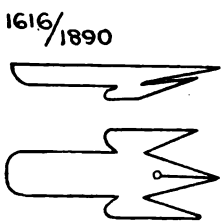

FIG. 18.

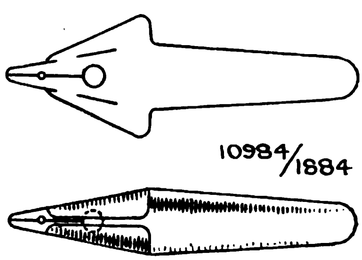

Sometimes a portion of the nib was so punched out that it could be folded over on the back of the nib, as in Fig. 19 (6824, 1894), and Fig. 20 (7,484, 1897). Or underneath the nib, as in illustrations Fig. 21 (A), and Fig. 22 (B),

FIG. 19.

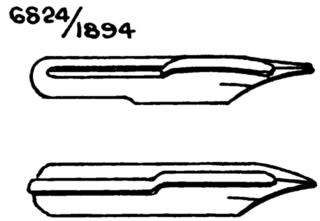

FIG. 20.

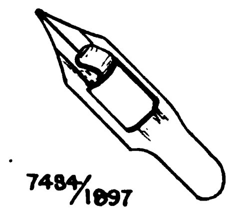

FIG. 21.

FIG. 22.

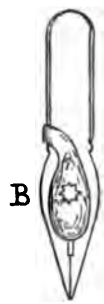

FIG. 23.

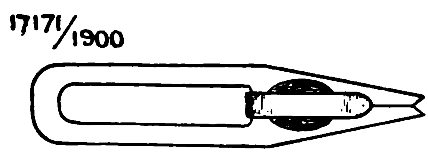

the space thus formed providing accommodation for a considerable quantity of ink. In some instances the folded part was used as a clip as in Fig. 23, to hold a pellet of aniline matter, so that on dipping the nib in water, a writing fluid resulted. Messrs. Perry and Co., some fifty years ago, introduced a similar

nib, having an aniline pellet cemented underneath, and these nibs were sold at what now appear to be very extravagant prices.

Not uncommonly nibs were provided with additional parts, which were either fixed by clips or other means, as shown by Fig. 24 (A), Fig. 25 (3818, 1883), Fig. 26 (12760, 1896), and Fig. 27 (13533, 1891), and also in Fig. 28 (503, 1891), Fig. 29 (17151, 1888), Fig. 30 (3204, 1900), Fig. 31 (10606, 1897), and Fig. 32 (3823, 1887, or were slipped into the penholder together with the nib, as shown in Fig. 33 (16516, 1888), Fig. 34 (12999, 1896), Fig. 35 (20862, 1895), Fig. 36 (21138, 1891), Fig.

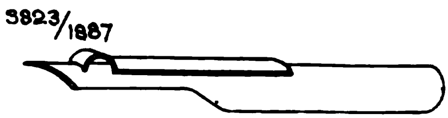

FIG. 33.

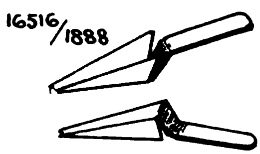

FIG. 34.

37 (A), and Fig. 38 (15309, 1886), or were part of the penholder, as in Fig. 39 (B). Another form was that in which the sides of the nib were bent into trough form, and a wire

FIG. 35.

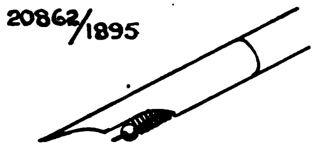

FIG. 36.

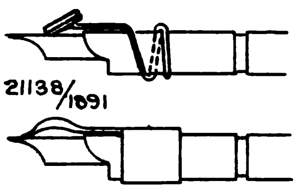

FIG. 37.

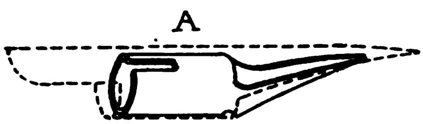

FIG. 38.

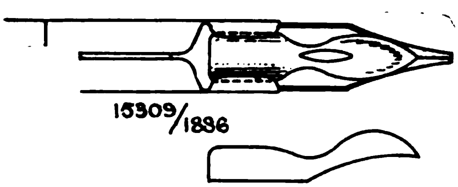

FIG. 39.

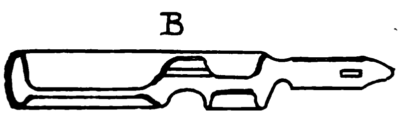

having a coiled loop was attached to the nib, lying along the bottom of the trough as in Fig. 40 (16235, 1891), or a fine wire was wound around the point of the nib, as shown in Fig. 41 (2328, 1889).

In the illustration Fig. 42 (155, 1883) we have a kind of barrel pen having a reservoir formed underneath the writing point, whilst the "barrel" may be inserted in a tubular holder containing a supply of ink which would gravitate to the point.

FIG. 40.

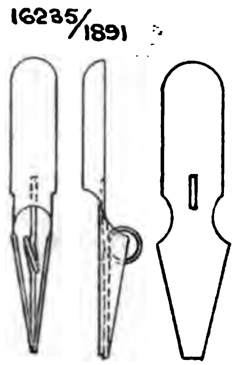

FIG. 41.

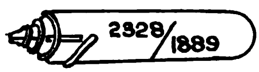

FIG. 42.

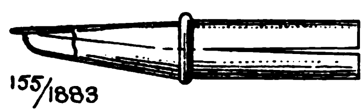

FIG. 43.

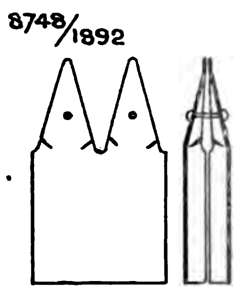

Illustration Fig. 43 (8748, 1892) shows a barrel pen formed from a flat piece of steel, bent into a tube, tapering towards the point. And the adjoining illustrations Fig. 44, (13665, 1888), show a somewhat similar pen, having four points meeting to form the writing point. The illustration, Fig. 45 (18020, 1899), shows a trough formed underneath the nib.

Several inventors have used India rubber in combination with nibs as a means of holding ink. In the first example, Fig. 46 (3808, 1893), a tiny piece of thin sheet rubber is punched

FIG. 44.

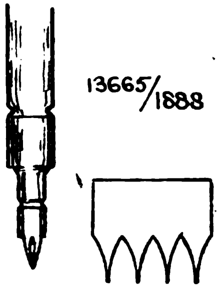

FIG. 45.

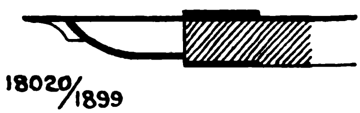

FIG. 46.

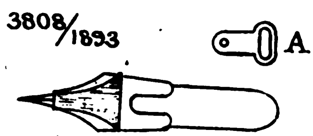

FIG. 47.

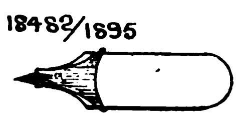

FIG. 48.

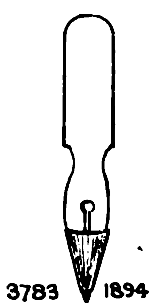
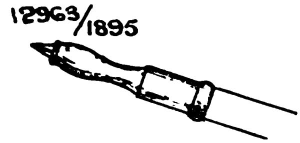


out, as shown at A, and this is fitted to the nib by inserting the point into the openings provided. The next example, Fig. 47, is very similar (18482, 1895). In the next illustration, Fig. 48 (3788, 1894), a short piece of india rubber tubing is used; and in the fourth example, Fig. 49 (12963, 1895), a nib, of barrel form, is almost entirely enclosed in a flexible

FIG. 49.



rubber tube, the point of the nib alone being visible.

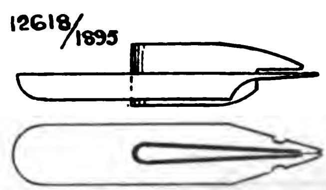
The remaining example, Fig. 50 (7241, 1897) shows a piece of flat rubber, the ends of which are held taut by a metal ring clasping them

FIG. 50.

to the penholder, whilst the point of the nib is just visible through a minute hole in the rubber.

In drawing Fig. 51 (12618, 1895) is shown a nib with an exaggerated "pierce" extending in tapering form about one-half the length

FIG. 51.

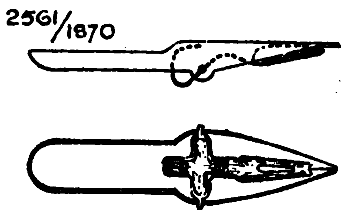


of the nib. Into this perforation is sprung a piece of flat metal, bent like a pair of forceps. It is possible that a considerable quantity of ink might be held here, but the pen is too clumsy to meet with universal approval.

The illustration Fig. 52 (2561, 1870), shows an addition to a nib, having a kind of counterpart pivoted underneath, and held in

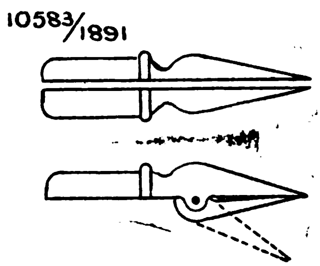
position against the nib by a tail spring. Although patented in 1870, this has recently been offered as a novelty.

FIG. 52.



A more recent patent, Fig. 53 (10583, 1891), is also illustrated here, in which two nibs are held together in a holder, face to face, the

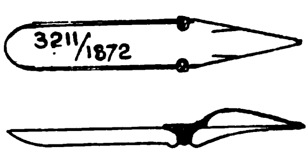
FIG. 53.



cavity forming an ink reservoir; and another drawing shows the lower nib pivoted into the upper one, suggestive of a bird's beak.

In Fig. 54 (3211, 1872) we have a nib which it is convenient to refer to here, although it was not primarily intended for a reservoir nib. The nib proper has no slit, but the combina-

FIG. 54.



tion of its point with the point of the overhanging plate (which, it will be observed, projects slightly beyond the nib point) forms an elastic writing point, the ink being delivered from between the two points, the object being to produce a pen having the sensation of a quill in writing.

The foregoing examples are merely typical, and do not by any means exhaust the number of attempts to produce a reservoir nib. Some of them are very well in their way, and some are ingenious. They obviate the necessity of frequent dippings in the inkpot, for with some of them it is claimed that a letter may be written with one dip of ink.

So far so good, but something more is demanded. A lead pencil may be carried in the pocket, ready for use at any moment, where such an instrument is permissible. The aniline pencil came to meet a want, by supplying a more or less indelible marking agent. Ink, however, was not to be ousted, as, with its drawbacks, it is to-day the most suitable article for writing, a good ink being as permanent (and often more so) as the material upon which it is used. There was room, therefore, for some kind of pen which would carry a supply of ink sufficient to last a considerable time, and yet such a pen as could be carried in the pocket without risk of its being emptied where least wanted.

At this point I leave the subject till next Monday evening, when I shall give an account of the stylographic pen, showing by drawings, its invention, growth and vicissitudes up to the present time.

BRITISH RAILWAYS IN 1904.

The annual report giving the returns of the capital, traffic, receipts, and working expenditure of the railway companies in the United Kingdom* during 1904 has been recently issued by the Board of Trade. In general arrangement this report follows very closely along the lines of its predecessors, so closely in fact that the actual numbers of the pages in the return, in which information concerning specific systems is to be found, are identical with those in previous returns. There is an increase in regard to information published in 1902 in regard to the actual track mileage and length of sidings, and in future issues certain special information relative to electric railways is promised. Regarding all the railways of the United Kingdom as a composite system, the progress during the year is summarised under certain main headings, of which the most important are dealt with below.

Capital.—The total paid-up capital at the end of 1904 was £1,268,500, of which over £193,000,000 (about 15 per cent.) is due to nominal additions through the consolidation, conversion and division of stocks. The increase during the year amounted

* No. Cd. 2523. Wyman and Sons, Limited, Fetter-lane, E.C. Price 1s. 3d.

to £23,500,000, of which £2,300,000 was due to nominal additions. The average dividends paid on the various classes of capital in 1904 were practically the same as in 1903, being 3¼ per cent. on the ordinary capital, 3½ per cent. on the preference, 4 per cent. on the guaranteed, and 3½ per cent. on the debenture stock, while the rate of interest on loans was 4·11 per cent. The mean average dividend on interest on the total capital is 3·42 per cent., but if no nominal additions had been made this would have been 4·03 per cent.

Total Traffic and other Receipts.—The total traffic receipts amounted to £103,787,000 (£55,400,000 from the passenger and £48,387,000 from the goods services), while £8,045,000 was received from rents, tolls, navigation, steamboats, hotels, canals, &c. The traffic increase during 1904 was very small, being 0·9 per cent. from passengers and 0·5 per cent. from goods.

Passenger Traffic.—The items of chief interest are those which show that the receipts from ordinary first-class passengers amounted to £3,429,000 (or £99,000 less than in the preceding year), from ordinary second-class passengers to £3,265,000 (or £67,000 less), from ordinary third-class passengers to £29,382,000 (or £109,000 more). This nett loss on ordinary traffic has been balanced by increased receipts from season ticketholders, a gain of £138,000 towards the total season ticket revenue of £3,999,000; and by increased receipts from the miscellaneous sources of express luggage, mails, parcels, carriages, horses, dogs, &c., which yielded a gain of £338,000 towards a total revenue from these minor sources of £8,322,000.

Season Ticketholders.—Towards actual receipts, the third-class holders of season tickets contributed rather more than three-eighths, for more than half the number of holders, the following Table giving the chief items of interest under this head:—

Class.	Gross receipts.	Number of ticket holders.	Average cost of each ticket.
	£		£ s.
First	1,437,000	130,789	11 0
Second ...	1,038,000	169,272	6 3
Third	1,513,000	343,812	4 8

Goods Traffic.—As regards tonnage carried, the weight of minerals carried increased by 5,900,000 tons to a total of 349,600,000 tons, while general merchandise only increased by 300,000 tons to 100,300,000 tons. The respective revenues earned by these sources amounted to £25,672,000 for minerals, and £28,315,000 for general merchandise.

Working Expenditure.—Despite a decrease in the expenditure on coal for, and general maintenance of, the locomotives used, the working expenditure for 1904 was £610,000 greater than 1903, amounting in all to £69,170,000, or 62 per cent. of the gross receipts. Over one-third of the increase mentioned above is due to rates and taxes, which have increased by £243,000, reaching the huge total of £4,736,000, or more than 4 per cent. of the yearly gross earnings. There is no sign of any diminution of this burden, which in nine years has risen from £3,011,000 to £4,736,000, an increase of over 60 per cent.

THE GERMAN TARIFF.

When in 1875 Prince Bismarck reimposed the corn duties which the German Zoll-Verein abolished in 1865, his primary object was to render the Empire financially independent of the various confederate States. But both then, and since, when the tariff has been raised, it was hoped that it would make the German food supply independent of foreign countries. This aim has not been attained. Probably no one, not even Prince Bismarck, anticipated the enormous increase in the population of Germany that has taken place during the last thirty years. Be that as it may, in the course of the last ten years, Germany has been dependent on foreign supplies for 2·7 to 11 per cent. of her rye consumption, 25·8 to 50·5 per cent. of wheat, 24·5 to 34·3 per cent. of barley, and 1·8 to 9·9 per cent. of oats. The imports have fluctuated in accordance with harvest results, and changes of prices, but there remains a considerable increase. As for the import of cattle and meat, it has been practically stopped by the pressure put upon the Government by the Bund der Landwirthe (Union of Farmers), and under the new tariff, which comes into force on March 1st next, it is hoped to do for corn what has already been done for cattle and meat. It may be interesting to compare the existing tariff per ton of 1,000 kilos with the one coming into force next March:—

	Under existing tariff.	Under new general tariff.	Conventional tariff.	Wholesale price at Berlin per ton of 1000 kilos.
	£ s.	£ s.	£ s.	£ s. d.
Rye	1 15	3 10	2 10	7 2 6
Wheat	1 15	3 15	2 15	8 18 6
Spelt	1 15	3 15	2 15	..
Barley (malting)	1 0	3 10	2 0	8 15 0
„ (other)	1 0	3 10	0 13	7 0 6
Oats	1 8	3 10	2 10	6 18 5

The conventional tariff applies to imports from countries having most-favoured nation treatment.

In the course of the last twenty years, the area under cultivation of cereals and potatoes in Germany has not undergone large changes. As regards wheat and barley, it has remained practically the same. The staple bread stuff—rye, had in 1884 an average of 5,850,000 hectares, which increased to 6,040,000 hectares in 1894, and after falling below 6,000,000 hectares in the following years, and passing it again

in 1902, stood at 6,100,000 hectares in 1904, *i.e.*, about 4 per cent. higher than in 1884. The area in oats shows a larger increase as from 3,780,000 hectares in 1884, to 4,190,000 hectares in 1904, or about 11 per cent. It remains to be seen whether the very much higher tariff, soon to come into operation, will be more successful in its purpose than that now in force. That the agrarian duties have failed to assist the agrarians generally is less surprising when it is remembered that 75 per cent. of all the cultivated land is in the hands of landed proprietors owning estates below five hectares in area. Such owners if they produce corn at all produce it for their own consumption, and the agricultural products which they take to market are of a different kind, such as vegetables, fruit, &c., which yield them a better return. In his report on the trade of Germany for 1904 Mr. Consul-General Oppenheimer has some very interesting observations under this head. He says that the effect of the duty is smallest where it is most required. Corn duties were meant to protect more particularly the small owners, but in fact the effect of the duty varies with the size of the holding and has least effect where it is most wanted. The smaller the farm the greater will be the ratio of home consumption of self-grown corn, whether as food of the family and the farm hands or as food for cattle. Even if these farms sell corn shortly after the harvest they are obliged to buy it back later in the shape of bread, flour, &c., and they are then compelled to pay the price which has been increased by Customs duty, commercial profit, interest, &c. The agrarian and the industrial duties differ considerably in their effect. The larger the percentage of the harvest sold the higher will become the rate of the Customs duty, so that the smaller the landed proprietor the smaller is also the protection he enjoys, and the larger the estate the larger becomes also the protection. With the consumer it is the reverse. The smaller his income the larger is its share which is consumed by bread and flour, and the more acutely does he in consequence feel the weight of the duty. In both cases the duty, according to this argument, presses most heavily on the small man. Nor must it be forgotten that the duties upon fodder, cattle, &c., weigh heavily upon the agrarian. There is hardly an agricultural holding which is not compelled to buy additional fodder for the breeding and fattening of cattle, and stock breeding in Germany being insufficient a considerable number of stock cattle have to be imported from abroad.

ADMIRALTY CHARTS.

The following is the official list of charts issued by the Hydrographic Department of the Admiralty in July and August last:—

New Charts.—3506—North sea:—Aussen Jade and and Schillig road. 124—North sea, Netherlands:—Texel. 3516—Norway, west coast:—Nord fiord to Indvik fiord. 3499—Sweden, Norrköping bight:—Landsort to Haradskar. 2362—Sweden:—Landsort to the gulf of Bothnia. 3505—Baltic sea: gulf of Bothnia:—Khögklubb to Goskällen. 33—Germany: Elkernförder Bucht and Kiel fiord. 2714—Portugal, west coast:—Port Setubal. 3482 — Nova Scotia, south-east coast:—Shelburne harbour. 1001—Africa, west coast; plans on the west coast of Africa; plan added:—Dakar. 3030—Bays and anchorages on the south coast of Java; new plan:—Chi Lauteureun bay.

Charts that have received additions or corrections too large to be conveniently inserted by hand, and in most cases other than those referred to in the Admiralty Notices to Mariners:—

No. 1826—England and Scotland, west coasts:—Formby point to Kirkcudbright. 2676—Scotland, west coast:—Loch Alsh and Loch Duich. 1607—England, east coast:—River Thames; North Foreland to the Nore. 2484—England, east coast:—River Thames; London to Gravesend. 1610—England, east coast:—North Foreland to Orfordness. 1491 — England, east coast:—Harwich Harbour. 1543—England, east coast:—Yarmouth and Lowestoft roads. 120—North sea:—River Schelde, from the sea to Antwerp. 2593—Germany:—Ameland to Jade river. 3346—Germany:—Jade and Weser rivers. 2305—Norway, sheet III.:—Stav fiord to Romsdals islands. 3101—Norway:—Atleö to Batalden, including the entrance to Stav fiord. 3118—Norway:—Batalden to Vaagsö. 1145 - Norway:—Vaagsö to Skerpen. 1146—Norway:—Rövde and adjacent fiords. 3038—Norway: — Biörnsund to Kristiansund. 2314—Norway, sheet XII.:—Helgö to Sörö. 2315—Norway, sheet XIII.:—Sörö to North cape. 2316—Norway, sheet XIV.:—North cape to Tana fiord. 2317—Norway, sheet XV.:—Tana fiord to Varanger fiord. 2252—Baltic sea:—Gulf of Bothnia. 3503—Germany, north coast:—Gulf of Danzig, western port. 2835—Black sea:—Delta of the Danube. 517—Central America, east coast:—Porto Bello and the adjacent coast. 2544—South America, east coast:—Rio de la Plata. 1749—South America, east coast: — Monte Video to Buenos Aires. 1325—Chile:—Gulf of Peñas to the Guaytecas islands. 650—Africa, east coast:—Plans on the east coast of Africa—Innambán river, Kilimán river. 1003—Africa, east coast: — Pungue river, Beira harbour. 2599 — Red sea:—Jidda with its approaches. 1419—Andaman islands:—Long island to Port Blair. 2576—Borneo:—Sulu archipelago and the north-east coast of Borneo. 3449—China, east coast:—Amoy, outer harbour. 1798 — China, north coast:—Kwang tung peninsula. 451—Japan:—Yezo island with adjacent straits of Tsugarau, La Perouse, and Yeso. 2411—New Zealand:—Otago harbour, from the entrance to Dunedin. 2540—New Zealand:—Awarua or Bluff harbour.

These charts are issued by Mr. J. D. Potter, 145, Minories.

HOME INDUSTRIES.

Liverpool and Cotton Spinning.—Some short time ago there was a movement in Liverpool to get rid of London as the distributing centre for tea. Many solid arguments were adduced to show that Liverpool would be a considerable gainer by importing direct. Now there is a scheme afloat for the erection of cotton mills at Liverpool. Liverpool merchants say that more and more cotton is going to Manchester which used to come to Liverpool, and that unless the tendency is stopped Liverpool will ultimately lose its cotton import trade altogether, that is to say, the greatest of its commercial interests. It is the old grievance of the Manchester Canal injuring Liverpool trade. The immediate proposal is to spend £1,500,000 sterling in erecting cotton mills at Liverpool with 500,000 spindles. These mills would be the largest and most complete in the world if the intentions of the authors of the scheme were carried out, and all the various operations of spinning, weaving, bleaching, dyeing, and printing would be concentrated at Liverpool. There seems no sufficient reason why Liverpool should not spin cotton as well as import it if it thinks it to its interest to do so, and it is natural it should be of that opinion. It must be annoying to see ships sail by Liverpool with the bales they were formerly in the habit of unshipping there, and if Liverpool cotton mills would stop them from making for Manchester so much the better for Liverpool. There does not seem much in the contention that Liverpool weather is too dry for cotton spinning. Whether the project will ever get beyond the discussion stage remains to be seen. Liverpool is less ready than Manchester for large and costly experiments, but the desire to checkmate Manchester, and the growing appreciation of the risk attached to relying so greatly upon the shipping trade, may carry the scheme to fruition.

The Boot Trade.—Last year, 876,756 pairs of boots were imported into the United Kingdom from the United States. It is an immense number, but in 1901 over a million pairs—to be exact, 1,028,364 pairs—were imported from America, and this year the import is likely to be much less than in 1904. The way in which the British manufacturer pulled himself together in face of American and other competition—in 1901 Belgium sent us 1,192,656 pairs, in 1904 678,828 only—shows that there is a good deal of fight left in him. The American boot manufacturers got a hold in this market by offering a boot no better, perhaps not so good, as the British article from the point of view of durability, but much smarter to look at. The purchaser often prefers appearance to more solid merits, especially when it is combined with cheapness. The British manufacturers met this fresh development of American competition by giving their attention to appearance whilst not neglecting wearing quality. They copied the smartest American models and began to pay great attention to finish and appearance. The result is that they are rapidly recovering the market they lost by ignoring the demand for a good-looking as well as a good wearing boot. Probably there is no trade in the country that now gives better value for money than the boot trade in its cheaper branches, but this can hardly be said of the West-end bootmaker, who adheres to a scale that has little relation to value.

Trade Marks.—A case which should be of interest to traders and patentees in the United Kingdom has recently been decided in the United States Circuit Court in the northern district of New York. It is that of "Siegert *v.* Gardolfi." The plaintiffs sought to restrain the defendants from using the words "Angostura Bitters" as a trade mark. Messrs. Siegert were the original makers of these bitters, and adopted the name of "Aromatic Bitters," but the public generally came to call them by another name, "Angostura Bitters." The question at issue was whether, having registered the trade mark "Aromatic Bitters," which had given place to the unregistered name "Angostura Bitters," Messrs. Siegert had any exclusive right to the use of the better known name. The American court has decided that they have not, that they may not, by adopting the name as their own after other makers have used it to designate their products, obtain any exclusive right to it as a trade mark, or trade name.

Cotton Supplies.—It is much to be regretted that the movement started by the British Cotton Growing Association for promoting the cultivation of suitable qualities of cotton in Britain over-seas is so greatly hampered by lack of capital. The Association was founded under very influential auspices. Its lists of vice-presidents included no less than 22 members of Parliament, and among its supporters were some of the best known names in Lancashire. Moreover the danger of remaining largely dependent upon the United States for the Lancashire cotton supply, a source of supply that is yearly more drawn upon by continental countries and the United States themselves, is so menacing that it was hoped that the funds necessary to give the required impetus to the growth of cotton in British colonies would have been forthcoming. Unfortunately that has not been the case. The abnormal cotton crop of the United States last year, by removing all immediate danger of insufficient supplies of the raw material, deprived the movement of much of the support that might otherwise have been given it, and at present the outlook for the Association, and what is much more important the national work with which it has concerned itself, is anything but hopeful.

Cotton Within the Empire.—It is a little strange that although during the last five and thirty years an

rea of nearly 5,000,000 square miles has been added › the British Empire, a good deal of it quite suitable ›r cotton growing, the quantity of cotton produced ı various parts of the Empire has increased very owly. Fifteen years ago the production amounted ı all to 2,357,304 bales, and in 1903 it had only ıcreased to 2,628,206 bales. More than nine-enths of it comes from India, but the Indian roduction, which was 2,346,121 bales in 1889, as only 2,624,948 bales in 1903. And yet India lone might easily supply the cotton require-ıents of the world. The estimated require-ıents of the cotton spinners of qualities equal to ıe American produce at present, may be put at 1,500,000 bales. A bale contains 500 lbs. of cotton, › that at present the acreage required for cultiva-on is about 28,000,000 acres. The area in the Inited States which can be economically devoted to otton is not thought to be more than 35,000,000 cres, which is small compared with the area that ıight be profitably devoted to the cultivation of otton in India, with its total cultivated area of 26,000,000 acres. Of course, India has its own equirements to meet, but the surplus available for xport might be increased enormously, if only rowers could be induced to cultivate the right ualities. The American crop of the present year bids ıir to reach 11,000,000 bales, and as the Egyptian rop is a record one, and that of India likely to be ear the average, any immediate scarcity is not antici-ated, but that is no good reason for slackening ffort to lessen the present dependence upon the Inited States, although it is to be feared it will have hat effect.

Synthetic Indigo.—The increased sales of synthetic ıdigo bid fair to destroy the old and important Anglo-Indian industry of indigo planting. Since 895-6 the value of the exports has fallen from £3,569,700 to £556,400, and this is largely due to ynthetic indigo. Of the indigo imports of Japan last ear fully three-fourths was the artificial product, vege-able indigo being increasingly unsaleable, in so nuch that some 1,000 cases had to be re-exported. n the United States the synthetic die came on the narket in 1898 and was held at 44 cents. per pound, ıbout the value of vegetable indigo on the indigotine ›asis. Now the price is down to 18 cents., and at his figure it is claimed to be much cheaper than the owest obtainable values in any vegetable indigo. The ırtificial die has already secured nearly 85 per cent. of he world's consumption, and the price of indigo has lropped about one half. The production of synthetic ndigo was known long before it could be produced n a profit-yielding manner. The credit of its dis-covery is due to Germany. The search after the new process of manufacture swallowed enormous sums of money which only wealthy houses could have afforded to spend without any immediate prospect of profit. And a general campaign had to be taken against natural indigo all the world over. The result as it affects the vegetable product is indicated above, and in the fact that to-day Germany imports only small quantities of natural indigo while her exports of synthetic indigo have increased enormously, and represented last year a value of 25,000,000 marks.

A Dwindling Industry.—Although the complaints of cabowners have been loud ever since cabs were first invented for the use of the public, there can be little doubt that the cab industry must be reorganised if it is to retain any measure of prosperity in London. It is said that the metropolitan hansoms are diminishing at the rate of 600 a year, and their shrinkage is likely to continue at an accelerated rate. For the cab has no longer the monopoly which, in the opinion of many, it so greatly abused. The electric tram, the motor omnibus, the tube, the electrified railway, all offer means of locomotion equal, or superior, in point of speed to cab transit, and infinitely cheaper. Even the four-wheeler has to reckon with formidable competition from the railway companies. Whether anything can be done to restore the cab to its old supremacy is doubtful, and the men alienate sympathy by their refusal to accept the taxameter. It may be noted that at a crowded meeting of cab drivers, very representative of the trade, held last week, the men would not even discuss the advisability of accepting the taximeter. Why? Can it harm them unless it harms them by making it impossible to charge an illegal fare? Be that as it may, it seems pretty certain that if the present system of hiring horse and cab to the driver is to be continued the owner will have to accept less than his present demand, and it is worthy of note that in Germany he only receives on an average 7s., as compared with 11s. 3d. in London. Probably the time is not distant when cabs not belonging to great corporations will have to be driven by their owners if they are to be on the streets at all.

Beet Root Acreage.—The acreage in Europe sown to sugar beets must always be the principal factor in determining the price of sugar. The demand for sugar is constantly growing owing to the increase of population, and the higher standard of comfort. On the other hand the area under sugar cane cultivation increases very slowly. There is some slight increase in the cultivation in the British West Indies, and the expansion is more rapid in Cuba, but as compared with the growing requirements of the world, the increase in West Indian production is insignificant. Nor is there any striking increase elsewhere in the acreage under cane. It follows that if sugar is to continue cheap there must be steady and large increase in the area given to beet root cultivation. The following table, prepared by Otto Licht, the well-known sugar statistician, shows the position as it is affected by beet cultivation:—

Season.	Acres.	Season.	Acres.
1880-81	1,976,383	1901-02	4,849,881
1885-86	2,143,154	1902-03	4,415,667
1890-91	3,058,924	1903-04	4,338,892
1895-96	3,311,671	1904-05	3,980,358
1900-01	4,552,014	1905-06	4,643,037

It will be seen that the present year's area is the largest on record with the exception of that of 1901-02, and that it is 662,679 acres larger than that of 1904-05. Coupled with the larger Cuban yield of cane sugar, and average crops elsewhere, it would seem that the requirements of the market will be much better met this year than last.

GENERAL NOTES.

THE CONSUMPTION OF TOBACCO.—Some interesting figures are given by the Bureau of Statistics of the Department of Commerce, United States, respecting the *per capita* consumption of tobacco in recent years. Taking the principal countries of the world it has been as follows:—Belgium, 6·21; United States, 5·40; Germany, 3·44; Austria, 3·02; Canada, 2·74; Australia, 2·59; Hungary, 2·42; France, 2·16; United Kingdom, 1·95; Russia, 1·10; Italy, 1·05. Of course, the cost of the article, and its relation to the purchasing power of the individual consumer, have to be taken into account in noting the wide fluctuations in consumption in various countries. For example, in Belgium, whose consumption is the highest, the tax levied upon tobacco is the smallest of any country in the list. On the other hand, in Italy, where the consumption is the lowest, tobacco is taxed most heavily. Again, while the average consumption of tobacco in the United Kingdom is only 1·95 pounds as against 5·40 in the United States, the revenue raised from tobacco is almost as large in the United Kindom as in the United States. And in taking the *per capita* consumption as shown above, it has to be borne in mind that the majority of the population do not use tobacco at all. Probably not more than a fourth, certainly not more than a third, use it.

JAPANESE SILK.—How largely its leading staple, silk, contributes to the total value of Japanese exports is shown in Mr. Consul-General Hull's report on the trade of Japan, just issued (No. 3502, Annual Series). Taking the exports of Yokohama, which are considerably more than half of the whole country, they amounted in 1904 to the value of £17,355,829, four-fifths of which amounting to close on £14,000,000, belonged to silk. Most of the increase was in raw silk, of which nearly 13,000,000 lbs., of the value of £9,059,000, were exported in 1904, as against under 10,000,000 lbs., value £7,588,000, exported in 1903. The increase in the exports of silk from Japan in 1904 was abnormal, and the explanation must partly be sought in the conditions brought about by the war, which prompted the people to curtail home consumption in favour of foreign trade, with a view to increasing the resources of the country. Thus a considerable quantity of the staple which in former years found a market at home was last year diverted to swell the figures of the export trade. This movement was also largely facilitated by the increasing American consumption which last year absorbed an unprecedented amount of silk. At least two-thirds of the entire export went to America, and about one-half of this was exported by native companies.

PETROLEUM FUEL IN RUSSIA.—Respecting the shortage of petroleum fuel caused by recent events at Baku, the *Board of Trade Journal* reports that the Ministry of Ways of Communication have made over stock in their possession amounting to 4,000,000 pouds to the Volga Navigation Companies. The total shortage of fuel employed by industrial undertakings is estimated by the Ministry of Finance at 50,000,000 pouds, to meet which 90,000,000 pouds of coal are stated to be required. The production of coal in Russia, calculated at 1,000,000,000 pouds, is not, says the Finance Minister, sufficient to meet the increased demand. The Vistula and Baltic State Railways are stated to have decided to acquire 10,000,000 pouds of foreign coal.

THE LATE MR. G. A. THRUPP.—In the notice of the late Mr. G. A. Thrupp, which appeared in the *Journal* for September 8th last, Mr. Thrupp was credited with the foundation of the Coachmakers' Benevolent Institution, of the Institute of British Carriage Manufacturers, and of Technical Schools for Coach Artisans. Although he took a warm interest in all three bodies, the attribution to him of their foundation was hardly correct. The Benevolent Institution was due to a suggestion made by Mr. G. N. Hooper, at a dinner to the Chairman, Mr. J. W. Peters, of a Committee formed in connection with the Paris International Exhibition of 1855. The origination of the Institute of British Carriage Manufacturers was also due to Mr. Hooper's initiative, though Mr. Thrupp was an original member of it. The evening technical classes for coachmakers, founded in 1876, at St. Mark's School-rooms, Oxford-street, were the result of the joint action of Mr. Hooper and Mr. Thrupp, the former gentleman being Chairman of the Committee, and the latter the Honorary Treasurer. Both Mr. Hooper and Mr. Thrupp have done so much to promote the technical education of carriage builders, that it is a matter for regret that any error should have been made in the *Journal*, in attributing undue credit to either of them for their share in an important national work.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

RESERVOIR, FOUNTAIN, AND STYLOGRAPHIC PENS.

By James P. Maginnis,
A.M.Inst.C.E., M.Inst.Mech.E.

Lecture II.—Delivered January 30, 1905.

Stylographic Pens and Manufacture of Gold Pens.

It would appear to be a very simple matter to construct a pen capable of holding a generous supply of ink, especially if one makes it of the stylus form. Nothing perhaps could be more devoid of complications than, say, a glass tube of small diameter, having its one end drawn out to a tapering point, as here shown in Fig. 1. This tube may be filled with ink by placing its point in the liquid and exhausting the air in the tube, when the ink will rise up within it, and, if the opening at the point be sufficiently small, the ink will be held by capillarity in the tube. If the point be now drawn along a sheet of paper, a film of ink will be deposited in the shape of lines, or letters and words. Such a pen is frequently used in recording instruments, where a diagram line is produced automatically; but woe betide him who thinks he is in possession of a fountain pen which he can carry in his pocket and use at will. The laws of nature will assert themselves, and it is more than probable that on the first occasion upon which its proud fashioner and possessor takes it from his pocket to show to his envious friends, he will find that it has completely emptied itself of ink. Then he thinks that a cork or stopper fitted into the upper end would prevent a recurrence of such a mishap. It will, to a limited extent, but the warmth of his body—against which the tube lies—is sufficient to expand the air in the tube, and the ink is forced out through the point by this means. Other details are missing, and I have gone with considerable care into the very many patent specifications so as to be able to show how the ingenuity and skill of many inventors during many years have been applied to find the best solution of the problem as to how a stylographic pen should be designed.

Fig. 1.

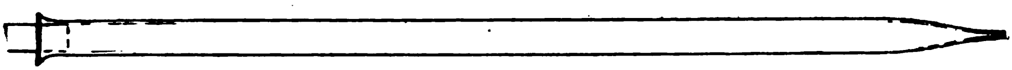

Fig. 2 is a drawing of a pen with a rigid point. It is formed of two pieces of wood carefully fitted and fastened together, having a thin tongue of brass placed between them, with the object of supporting a generous supply of ink. The wood is so formed that the points touch each other, and when the pen is charged with ink or liquid colour, bold lines, of the same width as the pen, may be drawn. In the example illustrated, the lines would be nearly half-an-inch wide. It is also possible to use this pen for bold writing, holding it diagonally,

Fig. 2.

as one would use a "J" pen, with the result that German text hand, or similar lettering, could be produced. With such an unprepossessing instrument, very creditable work can be executed.

A pen for a similar purpose is shown in Fig. 3, the operative part being made entirely of metal. It will be seen to consist of a flat plate at the base, whilst other plates, having their front ends turned downwards, are placed in succession above the flat one. At the back they are soldered together, and fixed in a wooden holder. The three intermediate plates have small perforations in them, and these

FIG. 3.

form a means of communication for the ink to pass from one space to the next, as it is wanted. These pens were introduced by Messrs. E. Wolff and Son, who named them the Auda-script Parcel Pens, and I have used them for at least thirty years, in the preparation of bold drawings, for which purpose they are admirably adapted. They are made of various widths, and lines of corresponding widths may be produced by them.

Fig. 4 is a somewhat similar pen, but of a modified design. It bears the name of a French firm.

FIG. 4.

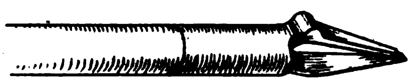

Fig. 5 is yet another of the same type as No. 3, but for fine work only. This bears the well-known name of Perry and Co.

FIG. 5.

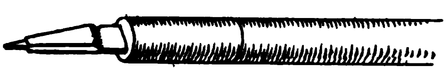

Fig. 6 appears at first glance to be very similar to the previous examples, but it differs in this respect:—The plates at their meeting

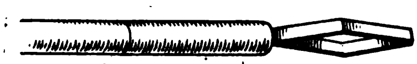
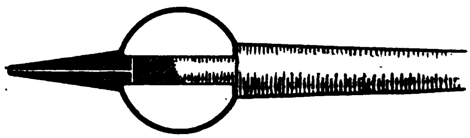
FIG. 6.



point are slightly serrated or grooved, in a graduated manner, so that on filling the pen with a rather thick gummy colour, the lines produced will have a shaded, or graduated effect, regulated by the depth of the serrations. The pen is Stoakes' patent.

A very simple form of pen, Marsh's patent, although not new, but still marketable, is that shown in Fig. 7. It is a self-filling pen. It consists of a tapering wooden holder, having a small bore hole, extending about an inch from the point, and branching off at a right angle, as shown in the section. The black circle represents an india-rubber ball, fitted on the holder as shown. On immersing the point in ink (having previously squeezed the ball and then released it), the ball becomes charged with ink, and the pen may be used for writing on parcels and the like.

FIG. 7.



In March, 1809, a patent (3214) was granted to Messrs. Folsch and Howard for a process enabling the user to produce two or more impressions by one effort in writing. The instrument described is made of glass, enamel, or any sort of stone or metal through which a hole can be drilled. The hole at the point of the pen is very small, but becomes larger a trifling distance therefrom. Common writing ink flowing from the point of the pen will give the first impression; the other copies are obtained by having previously placed alternate sheets of a transfer paper, described in the specification, and sheets of thin writing-paper, under that upon which the original writing was being executed. The pressure of the pen, acting as a stylus, reproduced the writing on the writing-paper, as is customary to-day in many places of business. The interesting feature, however, is that here is a fountain pen of the stylographic type described nearly 100 years ago. It is of the simplest possible form, without valves, needle, or other feed devices, simply a tube tapering at one end to a very fine pipette point.

Thomson's patent (12691) of July, 1849, shown in Fig. 8, consisted of a pen wholly made of glass, in which a piece of capillary tube, A, has a bulb, B, blown upon it at one end, the extremity of the bulb being drawn off into a curved form suitable for the writing point, C, the width of which and the opening

therein determine the thickness of the stroke produced by the instrument when in use. The bulb was filled with ink by suction of the mouth, or by other means of exhaustion. The same inventor also shows in Fig. 9 a piston, K, fitted to a pen of this description, to be used both for supplying ink to the bulb and also for charging the reservoir. The piston slides in a holder, A, and the glass bulb, B, having a short stem, S, is fixed into the holder by a suitable packing.

and soldered or otherwise fastened together at the other end to form a point suitable for use as a style. These wires were slightly separated midway between the ends so as to form a cavity capable of holding a considerable quantity of ink.

The pen shown in Fig. 11 is described by the inventor, H. B. Binks, in 1880 (1359), as being combined with a contrivance for retaining a quantity of liquid ink. It will be seen that it is formed of four wires, A, fixed in a holder, B,

FIG. 8.

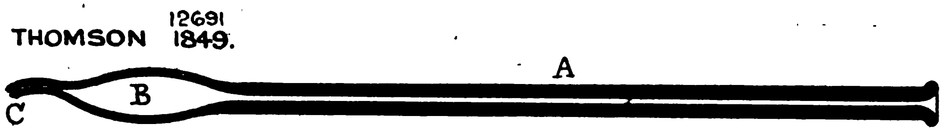


FIG. 9.

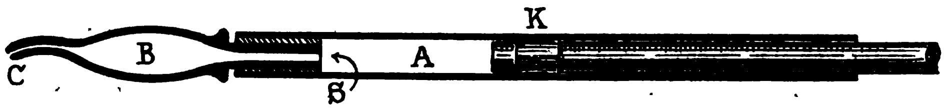

FIG. 10.

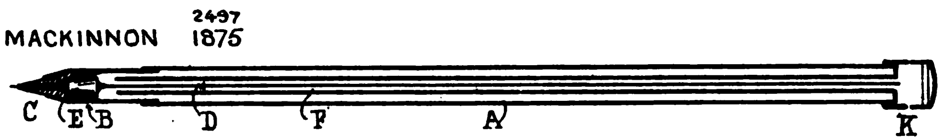
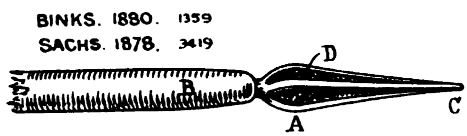


The pen shown in Fig. 10 (2497, Duncan Mackinnon, July, 1875), consists mainly of a tubular ink reservoir, A, closed at its upper end, and terminating in a point holder, B, at the other end. The writing point, C, may be of glass or any other suitable substance. It is bored centrally with a fine hole slightly tapering downwards. A fine wire spindle, D, extends the whole length of the pen, its lower end projecting slightly through the bore of the point, C, into which it fits almost exactly. The spindle, D, carries a weighted valve, E, in such a position that it rests on the seat formed to receive it in the point, C. Pressure on the point of the spindle when writing, will slightly raise the valve, E, and allow ink to pass to the paper. A small diameter dip tube, F, conveys air from the upper end to the ink reservoir. Air openings are provided in the cap, K.

A patent (3419) was obtained by W. Sachs in 1878, for a style formed of a group of four or five wires bound at one end into a holder,

and soldered together at the other end, C, so as to form a writing point suitable for manifold writing or marking. In this respect it is similar to that of Sachs, just described, as patented in 1878. The drawing was made from a

FIG. 11.

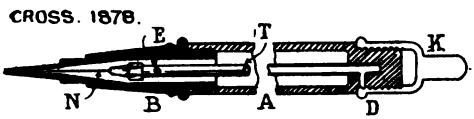


specimen in my own possession, and it is shown as having a bunch of fine wires of metal, glass, or asbestos, inserted in the cavity between the main members of the pen or style.

One of the successful pioneers of stylographic pens was A. T. Cross, who obtained patents (3640 and 4654) in 1879, in Great Britain. Fig. 12 shows a section taken from one of his stylographic pens in my possession, bearing

date 1878, this being probably the year in which his United States patent was applied for. It consists of a tubular reservoir, A, into which a point, section B, is screwed. The needle, N, is attached to the end of a small tube, I, extending the greater length of the reservoir.

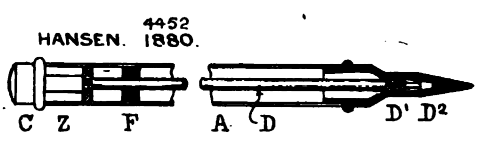
Fig. 12.



This tube admits air from the upper end, D, to a point, E, near where the needle is attached to it. The cap, K, at the end of the reservoir being partially unscrewed, uncovers the small opening leading to the air tube. The needle is not fixed in a rigid manner, but it is free to slide vertically in the box at the end of the tube. This box also contains a minute spring which tends to keep the needle slightly projected through the point of the pen, thus sealing it and preventing any escape of ink. In the action of writing, pressure of the needle upon paper slightly raises it, and in so doing, the ink is permitted to flow. These were amongst the first stylographic pens of a really practical nature, and were introduced into this country by Mr. C. W. Robinson, to whom much credit is due for the popularity of pens of this type. Mr. Robinson claims also to have been the first to suggest the word "Stylographic," as applied to these pens, and he says, Mr. Cross was the first maker to adopt the name.

In Fig. 13, Hansen's patent (4452) of November, 1880, a rod, D, is attached to the cover, C, and passes through the tubular holder, A. The

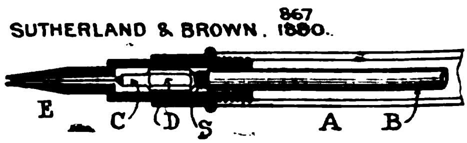
Fig. 13.



rod has an enlarged screwed portion, D¹, which screws into the point section to seal the point, and below this the rod is tapered to form the valve, D². To fill the reservoir the rod, D, is unscrewed and drawn up by the cover, C, and screwed into the socket of the piston, F, which piston is packed with rubber or leather. The piston is then used after the manner of a syringe, first placing the point of the pen in ink, which, by the action of the piston is drawn up into the holder. The rod is then unscrewed from the piston and pushed forward to the position shown. Sometimes the patentee fitted a washer or plate near the upper end of the reservoir to provide a stop to prevent the withdrawal of the piston, and to form an air chamber, Z. An air passage was formed along the rod to the point. Sometimes the rod, D, was made hollow in order to provide an air passage.

Fig. 14 shows a section of the stylographic pen of Sutherland and Brown, of February, 1880 (867). Into the reservoir, A, is screwed the point section, E. An air tube, S, fixed at its upper end, passes down the centre, and carries the needle or style. The latter consists of a fine wire slightly enlarged as shown

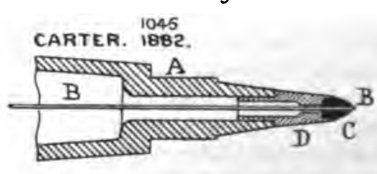
Fig. 14.



at C, where it is formed into a valve, and again at D, where it becomes of polygonal form, thus acting as a guide and a means of keeping the style steady, and permitting the ink to flow from the reservoir along its flat surface. Above this point it enters the air tube, B, freely sliding within it, whilst a light spring, S, tends to keep the valve, C, closed. During the operation of writing, pressure on the point raises this valve and permits the passage of ink.

The point of the stylographic pen is a matter that has had considerable attention bestowed upon it. In March, 1882, J. D. Carter (1045) was granted a patent, and a drawing in his specification is here reproduced in Fig. 15. To

Fig. 15.



render the point more durable he forms it of a jewel, C, mounted in a suitable setting, D, of gold or other incorrodible metal, the setting being burred at its outer end to secure the jewel therein. The jewel, C, is drilled to allow the needle, B, to pass through it, and the setting

D, is fixed in the holder, A, by shrinking the latter around it.

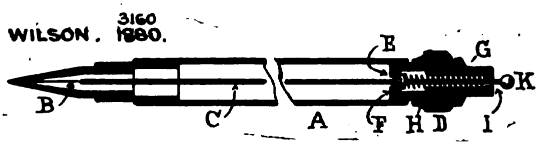
In July, 1880, N. Wilson patented a pen (3160) shown in Fig. 16, which he called the Wilson Stylus, one form of which was made entirely of metal. The construction was very simple. The holder, A, forms the reservoir, and into one end of this is firmly fixed the tapered point, B. A wire rod, C, extends the whole length of the holder, its point reduced in diameter, protruding slightly through the point of the pen. A hollow cap, D, is screwed into the other end, or top of the holder, and in this cap is formed an air chamber, H, and a vent, I, through which the rod, C, passes. A valve, E, formed on the rod, is forced down upon the diaphragm or valve seat, F, by the action of the spring, G, until automatically raised by the pressure upon the point of the pen in the act of writing. The rod, C, may be moved up and down by hand by means of the knob, K, at its upper extremity, for the purpose of clearing the ink duct.

when the cap is slightly unscrewed, and thence through an opening, to the ink reservoir. An aperture is formed in the screwed portion of the point section to allow of the escape of air from the reservoir as the point section is being replaced after filling the reservoir with ink.

In the penholder of J. Nadal, patented June, 1881 (2451), the reservoir is fitted with an air tube to which air is admitted by slightly unscrewing the cap, near the bottom of which there is an opening to admit air to the reservoir. The point section screws into the holder, and has an inner concentric sleeve, to maintain the air tube in a central position. This sleeve is formed with channels to allow the passage of the ink to the point section. A rod is fitted with a disc abutting on the end of the air tube, and with a valve, which by means of a spring prevents the passage of ink to the writing point until it is raised by the act of writing.

Mr. Massey-Mainwaring patented a pen in 1885 (8628), the writing point of which is in the form of a wheel, which rotates in front of the opening from the reservoir, as it is moved along the surface of the paper. This wheel is provided with a circumferential groove, and several radial grooves, which, as the wheel rotates, cause a needle to move up and down, and so produce a constant flow of ink. Such a pen as this must be better adapted for ruling or marking than for writing.

FIG. 16.



The Livermore pen (see Fig. 45, p. 1157), was introduced into this country in 1880 by Mr. Robinson, to whom I have already referred. The slide is taken from a descriptive printed sheet which was issued with the pens by the manufacturers. It will be seen that air is admitted by slightly unscrewing the cap, A, thus permitting the small opening to be uncovered, and allowing air to pass down the central tube to the point, J, where it escapes into the ink reservoir, C. The needle, G, is of gold, and is kept in its forward position by a minute gold spring, hidden within the silver spring box, F. The writing point is fitted with a tiny tube of platinum set in gold.

In the stylographic pen of M. H. Kerner, for which a patent (5733) was obtained in December 1882, the needle is fixed rigidly to the air tube. The air tube is reduced in diameter at the upper end, where it fits tightly in an india-rubber or other elastic washer, fitted in the top of the reservoir. The flexibility of this washer allows sufficient play to the needle in writing. Perforations in the cap admit of the passage of air to the air tube,

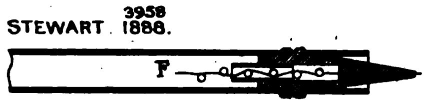
H. Holdsworth, in June, 1885 (7235), introduced a stylographic pen with a gold point, and a tip of ruby. The needle was made of gold wire, with an iridium tip, and was connected to a spiral spring. The inventor describes the top of the pen-holder as being loaded in order to prevent it from falling point downwards if accidentally dropped.

In the stylographic pen of S. A. de Normanville, who obtained a patent (14103) for it in November, 1886, the inner reservoir is elastic. It is closed at the upper end, whilst an ink conducting tube is fitted in the other. The pen or style fits in the tube, and is formed

of two half tubes conical at the writing end. A portion is slotted out to give the requisite elasticity, and also to admit air.

In Fig. 17 is shown a section of the stylographic pen of W. W. Stewart, who obtained a patent (3958) in March, of 1888, the chief novelty lying in his method of delivering ink to the writing point. He says that the

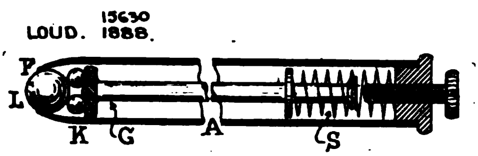
FIG. 17.



stylus may be a bristle, looped as here illustrated, and it will be observed that a bristle or horsehair extends from the writing point into the ink reservoir. This bristle is formed into a series of loops in order the more effectually to retain the ink and prevent a too rapid flow.

The instrument shown in Fig. 18 is not intended for use in writing in the ordinary way. In October of 1888 a patent (15630) was granted to J. J. Loud for the invention of a marking

FIG. 18.



instrument, specially useful for marking boxes or rough surfaces. The drawing shows that it is provided with a movable spheroidal marking point, L, fitting so as to revolve freely in the slightly-contracted mouth, F, of the tube, A. Above this are a number of anti-friction balls, K, held in place by the suitably-formed end of the rod, G, pressed into contact with these balls by the spring, S. A screwed plug, having an air inlet passing down its centre, is screwed firmly down upon the end of the rod, G, when the pen is not in use.

Chambers and Durant, in April, 1888 (5198), obtained a patent for a stylographic pen in which the ink reservoir was made of glass, a substance that would be very suitable for the purpose were it not of so fragile a nature. In Fig. 19, the glass reservoir, A, was a tube pointed at one end, and within this tube was a second tube, B, supported and kept central by two plugs, D and C. Passing through the tube, B, was a wire, E, having a loop, H, at one end and carrying a flexible wire, G, at the other end. In writing, the end, G, projects slightly through the point, and this was capable of adjustment by means of the loop, H, and of the wire, E. To protect the glass tube from injury it was enclosed in a metal casing, and caps, K and L, protected the ends.

Holt's specification (1708) of January, 1889, describes the pen shown in Fig. 20. The style or needle, K, is carried in a hollow spindle, G, which forms a valve at H, in the conical nozzle, C. This nozzle is secured to a plug, B, which screws into the ink reservoir, and is provided with an extension, D, into which screws a plug, F, which serves as a guide to the spindle, G. A spring, L, is placed between F and the collar, I, to press the valve, H, down on its seat. Air is admitted at the upper end through the small tube, N, which is screwed into the plug, M.

A method of obtaining an elastic needle or stylus is shown in Fig. 21, the invention of the before-mentioned Mr. C. W. Robinson, patent No. 3254, of 1890. The general arrangement will be familiar, ink being contained in the reservoir, A. Air is admitted through the small central tube, F, reduced in diameter at G, and attached to this is a short piece of flexible rubber tube, H, with a plug at its extreme end, into which is fixed the needle or style, I. The flexibility of the tube, H, allows the needle to rise, and forces it to fall, in the process of writing. The inventor also suggests that in placing the cap, K, in position, the india rubber plug, D, becomes compressed and forces air in the ink reservoir, and consequently expels ink at the point.

In Wattleworth's patent (2841) of February, 1891, we have a pen, shown in Fig. 22, in which the writing point, B, is made of a solid block of glass, having external longitudinally-arranged grooves along which the ink flows to its extremity. The inventor proposes that the ink reservoir, A, should also be made of glass, and be enclosed in a suitable casing, having a closing plug, C, at one end, whilst the writing point, B, is fitted in the other end. A section of the point, B, is shown also.

Here in Fig. 23 (5861) is another pen having a solid point, the idea of T. Jenks, who patented it in April, 1891. The point, B, takes the form of a grooved pyramid, and is loosely held in place by a metal collar, C, having claws, which permit of a slight vertical movement of the point. A light wire rod, D, is screwed into the point, and as the latter rises and falls the rod also does so, at the same time opening and closing the valve, E.

A nut is provided at L, by means of which the valve may be permanently closed, and the point may then be used as an ordinary style without ink.

Fig. 24 shows a pen with a curious internal economy, the invention of D. Doull, whose specification of April, 1891 (5926), states that to prevent leakage. When the cap is slightly unscrewed, air is admitted through a small hole, Q.

Fig. 25 shows the pen of C. P. J. Fitzsimon, patented August, 1891 (14329). The needle or style, E, extends from the writing point, through the upper end of the ink-holder, A.

Fig. 19.

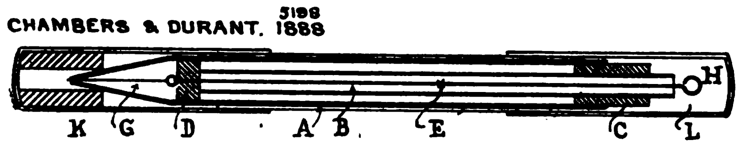


Fig. 20.

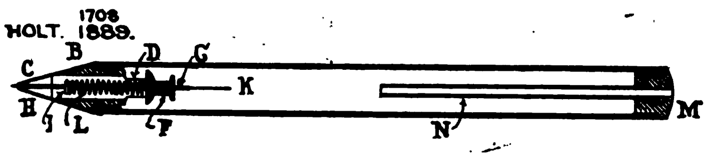

Fig. 21.

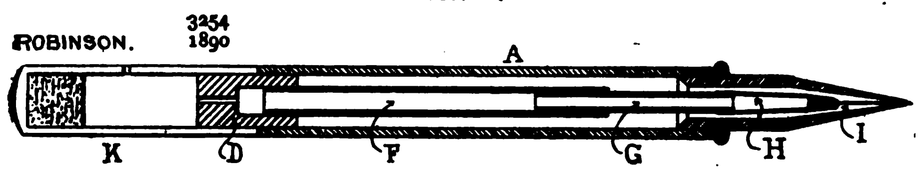

Fig. 22.

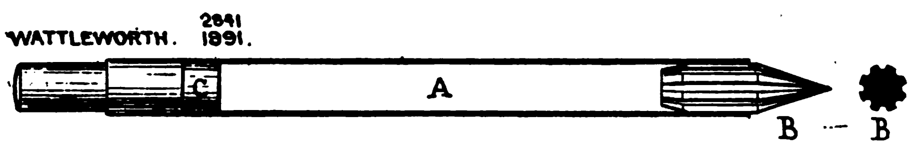

Fig. 23.

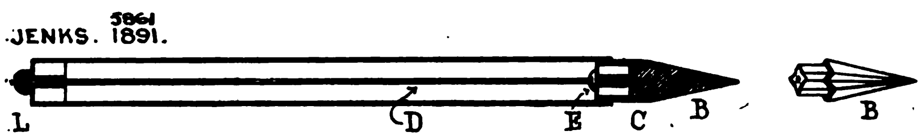

the style, D, is forced outwards by a spring, S, the pressure of which is regulated by the thumb screw, E, which actuates a screw-threaded ring, I, working in a threaded portion of the reservoir. The nozzle is shown at C^2, and is slit at the corners to give flexibility in writing. The cap is complex, having an inner part, H, screwing into the reservoir, and has an india-rubber washer, L, Two valves are formed on the needle as at, D, and D^1, which are forced down upon their respective seats by the spring, F, thus normally keeping closed the air passage and also the ink passage from the reservoir to the writing point. The enlargement near the centre of the needle is doubtless intended to act as a means of keeping it steady, and also for adjusting the valves.

FIG. 24.

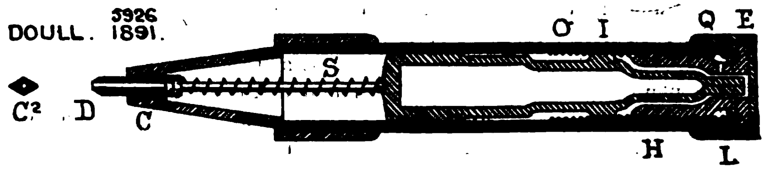

FIG. 25.

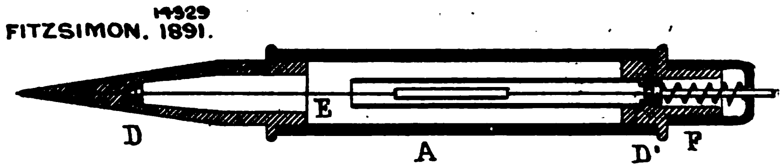
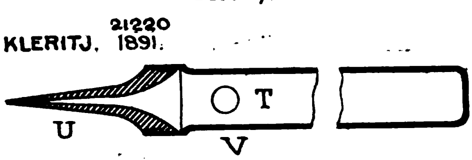


The next patent (19246, 1891) shown in Fig. 26, is that of G. E. Shand, who turned his attention to a detail of some importance in connection with stylographic pens, namely, a trap to prevent the escape of any ink finding its way along the air tube. In this invention, patented November 1891, it will be seen from

FIG. 26.

the section shown, that the pen is formed with an air chamber, B, at its upper end, and a short tube forms the continuation of the air inlet. Should any ink find its way into the air tube, E, it would continue its course to the air chamber, B, and would be prevented from escaping, although air is free to find its way inwards.

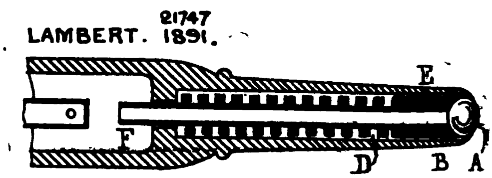
FIG. 27.



The specification of December, 1891 (21220), of L. Kleritj, relates to what he describes as multiple copying implements, useful also as a multiple writer, where fountain pens are used. The drawing, Fig. 27, shows a pen consisting of a tube, T, at the lower end of which is a tapering steel point, U, having a capillary passage. An opening is made at V, for the admission of air. Presumably this opening was covered with the finger in use. No mention is made as to the method of filling the reservoir, and it may perhaps be accomplished by unscrewing the nozzle, or point, U.

Fig. 28 (21747, of 1891) shows a section of E. Lambert's pen, in which a rolling point is used, as in that of Loud. The detail is, however, different, and it is thus described:—The writing point consists of a freely revolving ball, A, partly enclosed

FIG. 28.

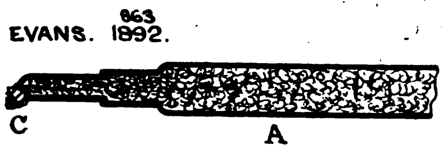


in the holder, B. The ball is kept in place by the bearing, E, of the piece, F, which is pressed against the spring, D. The inventor says that a large-sized instrument may be used for writing on canvas or wood. The ball may be made of vulcanite, or of a metal non-corrodible by ink, and the specification provides for the point containing the ball being in a plane inclined to the longitudinal axis of the pen.

The next pen shown, Fig. 29, the patent of T. Evans of January, 1892 (863), consists of a self-supplying instrument for writing or ruling purposes. As will be seen, the writing point consists of a small wheel or disc, C, pivoted at a convenient angle to the extremity of the holder, A, which latter is filled with an ink-saturated pad. The edge of the wheel, C, is

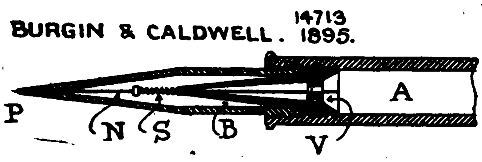
in contact with this, and as the wheel is rotated it picks up enough ink to deliver on the paper. This instrument would probably be more convenient for ruling or drawing lines, than for writing.

FIG. 29.



In Fig. 30, the patent of Burgin and Caldwell, August, 1895 (14713), there is not much that has not already been referred to. It relates to a pen in which the flow of ink is controlled by means of a valve, attached to a spring-held needle. The ink-reservoir, A, terminates in a

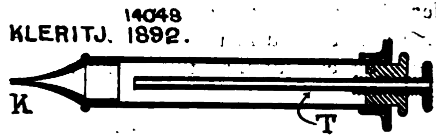
FIG. 30.



conical funnel, B, covered by a valve, V, attached to the needle, N. The free end of the needle projects slightly through the writing point, P. When pressed upon paper, the needle is pushed upwards against the pressure of the spring, S, the valve, V, is raised, and ink passes downwards to the writing point.

The next pen (14048, of 1892), illustrated in Fig. 31, is described by the inventor, L. Kleritj, as a "reservoir penholder suitable for so-called multiple writing machines," meaning thereby machines whereby two or more pens are controlled and operated by the movement of a master pen, by which means a corresponding number of writings may be obtained at one and the same time. Several patents have

FIG. 31.



been obtained for instruments of this kind. The pen in this case has a steel cone or point, K, with a capillary passage and an internal air tube, T. This tube is said to ensure uniformity of pressure, and to permit of the adjustment of such pressure.

Messrs. Mabie, Todd, and Bard have a stylographic pen which they call the "Cygnet." It is here illustrated in Fig. 32, and it will be seen that the needle action is of simple construction, and perhaps resembles that of the Cross pen more than any other. I have recently examined some of these pens carefully, and find they are as beautifully made as are the celebrated "Swan" pens, of which I shall have something to say later in connection with fountain pens.

Another device of A. T. Cross, patented in June 1896 (14093), is here shown in section, in Fig. 33, and in this the needle, N, is attached to a rod, C, having cross arms or guides, G, free to slide in the slots, S, in the ink reservoir, A. An air inlet, I, is formed between the writing point, P, and the point section, J.

FIG. 32.

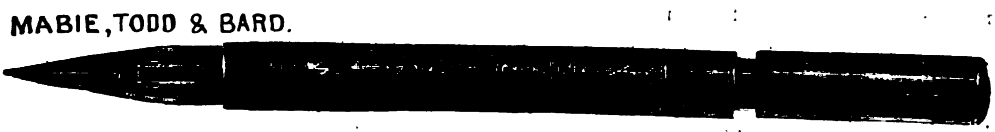


FIG. 33.

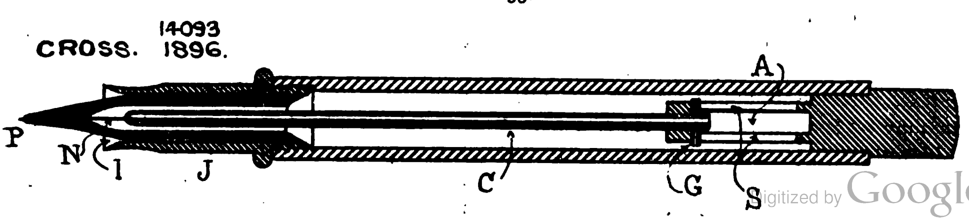

The drawing (Fig. 34) shows a pen, partly in section, devised by J. Hardcastle, and patented in June, 1898 (13455). Its principal feature is its self-filling arrangement. The reservoir, A, is fitted with a tubular plunger, C (or piston as the inventor calls it), open at its inner extremity. This plunger slides through a rubber stuffing-box, D. Filling the pen is effected by withdrawing the plunger, ink being thus sucked in through the opening, H. It will be evident that this plunger may be pressed home to the position shown after filling the reservoir, thus keeping the pen of a less unwieldy length than if the plunger were to remain in its extreme outward position.

FIG. 34.

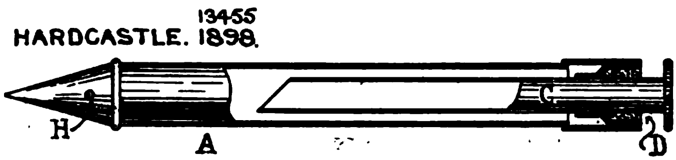

FIG. 35.

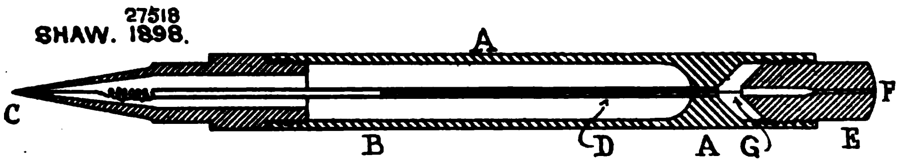

FIG. 36.

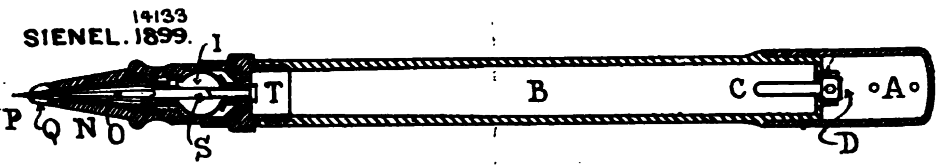

In W. T. Shaw's patent specification of December, 1898 (27518), the section shown in Fig. 35 is described. The ink reservoir, B, has a perforated diaphragm, A, into which is fixed the air tube, D. A screw plug, E, fitted into the end of the holder, is pierced with a small hole, F, for the admission of air, and it also carries a fine wire, G, which may be used in clearing ink deposits from the nozzle or writing point, C. Mr. Shaw considers that this principle may be applied to others of his pens. I would add that Mr. Shaw's name is identified with many other useful inventions connected with writing implements and materia Having myself been described as a "schemer," I would pass the compliment to Mr. Shaw, whom I consider to be a schemer of no mean order.

The pen shown in Fig. 36 differs in detail from almost all the others referred to, and is the invention of H. Sienel, July, 1899 (14133). The drawing shows a section of the pen. The writing point, P, is secured to a fluted cone, O, attached to a rod, S, which terminates in a tubular duct, T, to convey ink from the barrel, B, to the rubber ball, I. The conical chamber, N, terminates in the ink cavity, Q, at the point. Air enters through openings in the cap, A, and thence through the valve D, and the tube C, to the ink reservoir, B. The patentee states that the use of this pen tends to prevents writer's cramp.

Messrs. Doull and Doull again appear as the inventors of the new pen shown in Fig. 37 which was patented in June, 1900 (11310). It appears to be somewhat like another pen already referred to, in that the needle, I, owes its flexibility to the fact of its being indirectly attached to the flexible rubber tube, D. The air tube is held steady by the washer, F, through which it passes, and the needle may be adjusted in position, when necessary, by means of the knob A.

The pen shown in Fig. 38 (A. Dittmar, Aug., 1896, 18603), is perhaps unique. It consists of a capillary tube, B, tapering to a writing point, D, and the other end of which dips into the ink reservoir, E. I shall not attempt to describe the advantages to be derived from the use of this pen.

Prof. Dittmar, an electrician, collaborated for some time with Mr. C. W. Robinson, endeavouring to coat gold with iridium, with the object of increasing the durability of the needle it should be delivered very near the writing end of the stylograph. The needle should have just sufficient play or freedom to allow it to rise and fall with the greatest ease, neither more nor less. If this be properly adjusted, then the flow of ink is also as it should be.

An all-important matter in the use of pens of any description is the quality and suitability of the ink used. At home in large towns there is no difficulty in obtaining ink suitable for use in stylographic and fountain

Fig. 37.

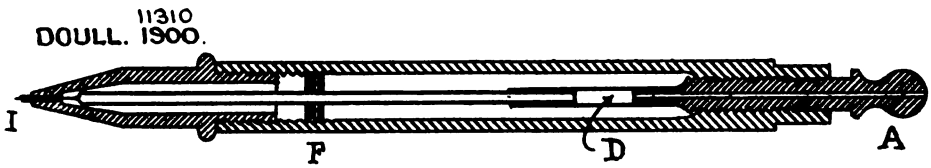

Fig. 38.

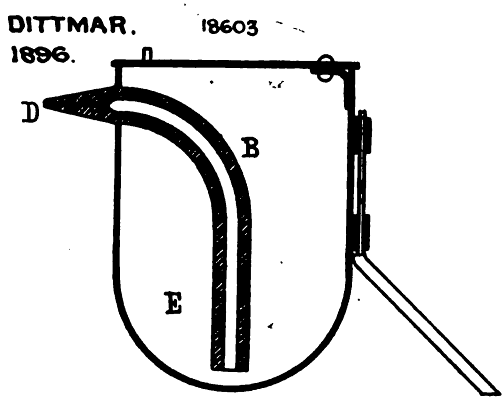


of stylographic pens—and with a certain measure of success.

A really good stylographic pen is not by any means to be despised. It has special merits of its own, and there are many persons who prefer it to a "nib" pen. If properly constructed it should permit a regular and even flow of ink when in use. To ensure this, the ink contained in the barrel should be held in perfect equilibrium, and as the ink is withdrawn in writing, the method of admitting air to take its place should be so beautifully designed that just sufficient air and no more be admitted. Experience has proved that it is best to admit air at the top of the barrel, and by means of properly-constructed passages

pens, but travellers abroad, and those who roam, cannot of necessity always procure the right ink just when it is wanted, unless, indeed, they carry a supply with them. It is not the fault of the makers of fountain pens if travellers omit to take this precaution, for suitable ink is offered by the makers, put up in the most convenient form possible. There is, however, an excellent alternative in the form of ink tablets—veritable homœopathic doses of solid ink, one of which is sufficient to charge a pen, the reservoir having been filled with water. These, in my opinion, add one more point, if such be needed, to the convenience afforded to those who carry a fountain or stylographic pen.

STYLOGRAPHIC PENS OF TO-DAY.

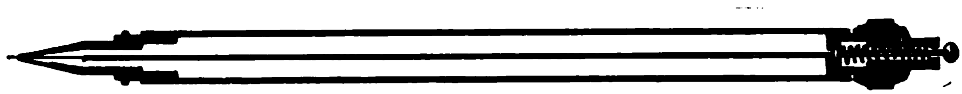
The invention of the vibrating needle-pointed pen introduced a revolution in the mode of writing, far more perhaps, than did the invention of steel or gold nibs. The great novelty and innovation on the then customary mode of writing, and their necessarily high cost when first introduced, stood very much in the way of their immediate acceptance as writing implements. As compared with the fountain pen (with its nib) the advantages claimed are, that it is much cheaper, and that the film of ink it distributes on the paper is so thin that it dries almost immediately. It is not, strictly speaking, a pen at all, but it has been more truly described as a fluid pencil, and the sensation of writing with a stylographic pen is very similar to that experienced when using a pencil. When properly adjusted it glides along smoothly and noiselessly, but in use the characteristic of one's handwriting is naturally more or less lost.

I have hitherto referred to stylographic pens in chronological order, that being the most convenient method for this lecture. There still remain a few which I have not yet described, which deserve a prominent place, on account of their excellence. These will be recognised in the following slides, which were photographed from a series of drawings I prepared some time ago to illustrate leading types of stylographic pens, and this fact accounts for a slight repetition of some of those already described.

The Wilson stylus, a complete section of which is shown in Fig. 39 has already been described (p. 1149), but a drawing of it happened to be included in this slide. It was made in vulcanite, as well as in metal, and I have some examples of these pens in both materials given me by their inventor. Those in metal are either nickel plated or gilt, and are objectionable on account of their weight, which is considerable for a pen. The inventor, however, Mr. N. Wilson, partner of the well-known firm of Wheeler and Wilson, deserves credit in that he set himself to produce a practical pen at a low price, and this he succeeded in doing, as his pens were sold in 1880 at half-a-crown each. One could not rely on them as pocket pens, for they soon acquired an unpleasant habit of leaking. Furthermore, the points were too soft and soon wore out.

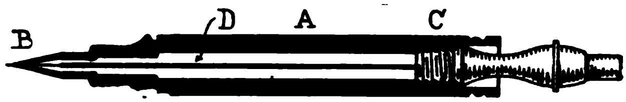
A provisional patent (3305), for the pen

FIG. 39.



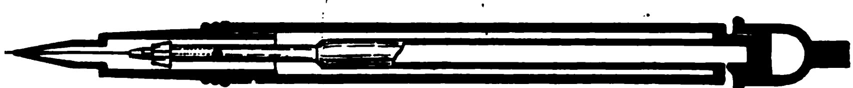
The Wilson Stylus 1880

FIG. 40.



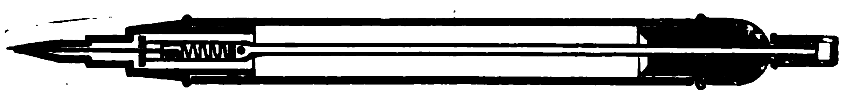
Kuttner's patent 1881

FIG. 41.



The Cross. 1878

FIG. 42.



Perry & Co's Styloidograph. 1879-1880

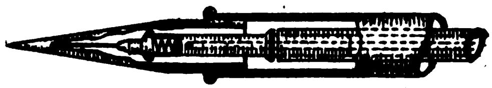
shown in Fig. 40 was obtained by J. Kuttner in July, 1881. This pen consisted of two parts only, and the section here shown in taken from an actual example in my possession. The reservoir, A, terminates in the usual manner, in a tapering writing point, B. An adjustable screw plug, C, screws into the other end of A, and forms a valve which may be opened or closed by screwing the plug out or in. A wire, D, of metal, and of uniform diameter hroughout, except at the extreme point, is ixed firmly in the plug C, and is just long enough to reach the point passing through a ninute parallel hole. In the act of writing, his wire vibrates to an extent controlled by he distance it protrudes through the writing point, this being regulated by the plug C, which simultaneously regulates the air supply o the ink reservoir. This pen point was, like hat of the Wilson stylus, too soft, and did not ast long.

In Fig. 41 is another drawing of the Cross pen, which has already been fully described (p. 1147), and I have nothing to add except, perhaps, to give the pen a word of commendation, in that one of these served me well for many years, and was only cast aside as a result of an accident.

About 1879 or 1880, Messrs. Perry and Co. ntroduced a very handsome-looking stylo-pen, which they called the "Styloidograph," and which is shown in section in Fig. 42. It was very similar in construction to the Cross pen, Fig. 42, having an air tube extending from the extreme upper end, and terminating in a spring box containing a piston or plunger to which the needle was attached. The barrel or reservoir was of richly-chased vulcanite, and the plug and cap, as well as the point section, were of gilt metal, presenting a smart appearance, which did not detract from its effective working.

Fig. 43 is a section of the point of a pen, advertised by Messrs. Burge, Warren and Ridgley as the "British Stylographic Pen," working on much the same principal as that of Cross. It will be noticed that the air tube is telescopic, thus forming a ready means of adjusting the position of the needle.

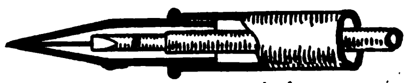
FIG. 43.



The British Stylographic.

In Fig. 44 the writing point of the stylograph known as the "Independent" is shown in section. The needle in this case is fixed rigidly in the end of the air tube, relying on its own flexibility for freedom in writing.

FIG. 44.

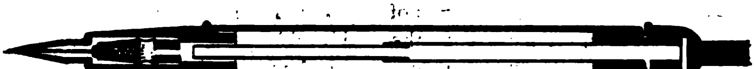


The Independent.

Mr. C. W. Robinson has a metal pen, made in 1868 by himself, in which the rigid needle is used as here illustrated.

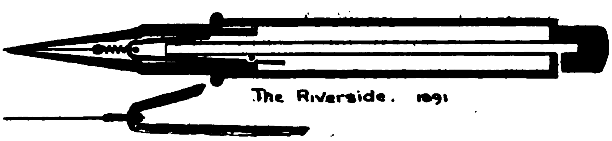
The "Livermore," has already been referred to on p. 1149. It is shown in section in Fig. 45, and it will be seen that the box carrying the spring, and the plunger to which the needle is attached, is a fixture in the point section into which it is screwed, and is not attached to the air tube as in previous examples. It was in its day a very excellent pen, but it is now seldom seen. One of these pens, which I carried regularly for some years away back in the early eighties,

FIG. 45.



The Livermore 1882

FIG. 46.



The Riverside. 1891

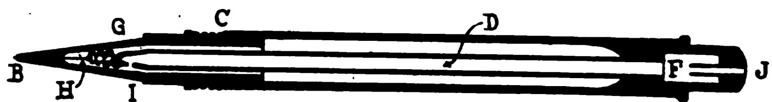
only failed as the result of falling on a railway platform some twenty years ago. This pen has now been repaired and is in perfect working order.

Fig. 46 shows a section of the "Riverside" pen. One of the advantages claimed for this pen lies in the method of holding the needle. A flat strip of silver is bent into the form shown below the pen, and passing through a hole in the fold is placed the needle, free to rise and fall with the spring. This combination is pushed into the point section, where it is held steadily by the effort of the silver strip, or yoke (as it is called), to expand, and the needle may readily be adjusted by raising or lowering the yoke as required. Although this ingenious little arrangement is here associated with the "Riverside" pen, I am under the impression that it is the invention of a Mr. Brown, whose name is well-known as the inventor of a fountain pen which I shall refer to in my next lecture. The "Riverside" pen is one of the specialties of the London Pen Company, founded by Mr. C. W. Robinson.

De La Rue's Stylograph.—This consists of the usual number of parts, viz., the cap, the point section, and the barrel, as shown in section in Fig. 47. The cap is similar to the caps of fountain pens, but is provided with a small pad or cushion of india-rubber, the object of which is that of a safeguard to prevent any possible leakage of ink from the point when the cap is in position. The point section is formed as shown, terminating in a tapering point, which again terminates in a very small metal tube skilfully inserted therein. The barrel is a vulcanite cylinder or tube into one end of which the point section screws, as shown at C, whilst into the other end (which is practically solid) is fitted a vulcanite tube, D, of small diameter, extending the entire length of the barrel. The end of this tube is open to the outer atmosphere through the chamber, F, and the hole, J; its other end, G, is sealed, and terminates in a short solid spindle upon which is fixed a coiled wire, extending forward in a straight line as shown at B. This wire is of such a diameter and length as to pass freely through the point, and just protrudes beyond B, when the point section is screwed home. One can readily recognise here the invention of Mr. Shaw of 1898, already described. Close to the sealed end G, of the air tube, there is a small hole I, which establishes communication between the interior of the air tube D and the barrel.

The pen being filled the ink runs down into the very restricted annular space between the wire, H, and the point, B, and thence on to the paper. At the same time air is being admitted through the chamber, F, and the air tube, D, to the opening, I, whence it bubbles up through the body of ink. In the chamber, F, is fixed a short tube open to the outer air at J. This tube forms an effective trap, as previously described, preventing the ink from leaking through the air vent, J, should a drop happen to find its way there, in case the pen be held in an inverted position.

FIG. 47.



The Nota Bene.

Altogether this is a very beautifully made instrument and one that I use continually for writing in manifold, I therefore speak from a practical experience extending over a considerable period.

I believe this pen is now called the "Pelican" Stylograph, by Messrs. De la Rue, the manufacturers of it, and as I have seen it being made I can testify to the great care exercised in its production.

Having now concluded my notes on Stylographic Pens, I should like to be permitted to assure those who have so attentively listened to me that I have throughout endeavoured to obtain the most reliable information on the various details described, and I have received very valuable help from gentlemen interested in the industry, as well as from Mrs. Robinson, to whose husband I have referred more than once this evening. It is more than probable, however, that errors may have found their way into my descriptions, in which case I shall be glad to be corrected, and to rectify any such errors. As I intimated last Monday evening I am not here to advocate any pen, but simply with a view to place on record what has been

done by busy inventors and workers to produce a satisfactory writing implement.

I now pass on to say a few words about gold pens and their manufacture.

To adapt the quill pen to modern requirements, as a writing implement, is impossible. In use, it has charms which kept it in favour for a very long time, but the disadvantages are great. It needs continual repair and attention, and it is not given to all to make a passable quill pen. Its life is limited. It soon wears out.

The steel pen is a great stride in advance of the quill. But a steel pen has serious drawbacks. The best steel pen will be quickly corroded by the acid found in many of our inks, or it will oxydize, and many a steel pen has to be discarded through one or other of these causes just as the writer is beginning to congratulate himself that at last he has a smooth-running pen with which he can write in comfort.

True, pens are frequently made of metals other than steel—alloys not so liable to corrosion. To meet the requirements of a good pen, such a metal must be flexible, durable, and proof against the action of corrosion and acid, and experience has proved that gold is the only metal which meets the case. It is, however, not pure gold, but is alloyed with silver, and thus reduced to 14-carat quality. This is almost universally adopted as the correct standard of fineness. There is another supreme quality required which the gold does not possess in a sufficient degree, and to obviate this defect the exceedingly hard metal iridium is called into service. The high price of iridium prohibits its use in making the complete pen of that metal; but it is recorded that about the year 1822 an English engineer, John Isaac Hawkins, discovered the advantage of attaching a fragment of iridium to the point of a gold pen, placing it in such a position on the point that it was the only part of the pen coming into contact with the paper in the process of writing. Iridium still continues to be the characteristic feature of all the best gold pens, though since Mr. Hawkins' time many improvements have been made in the methods of manufacture. Mr. Hawkins conducted a long series of experiments with a view to arrive at the best material to use. He tried rubies for the purpose, but these did not prove satisfactory. He cemented diamond dust to the points of quill pens, with even less satisfactory results.

It appears that after some thirty years of experiment, Mr. Hawkins heard of the failure of a pen-maker (Mr. Robinson) to make a pen of iridium, which he found too hard to work into shape. This fact encouraged Mr. Hawkins to give iridium a trial. The excessive hardness of the metal appealed to him, and in a simple manner he overcame the trouble. A very high speed lathe solved the problem. Using diamond dust and oil on a disc running at a very rapid rate, he found that he could cut into iridium, but even then very slowly, for a ruby could be cut in about one-third of the time. If then, iridium was say three times as hard as the ruby, he felt he had arrived at the right substance to give an absolutely durable pen point. But iridium was scarce. There was only one dealer in London at that time from whom it could be procured, and his stock was so small as to become quickly exhausted. However, there was sufficient of the precious metal to form points for a number of pens.

Thus the honour of originating the present and almost universal type of gold pen belongs to England, a trivial matter it may seem, but it has grown into an extensive industry.

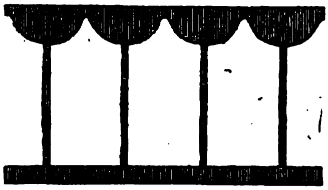
It remained for our American friends to invent various labour-saving machines and devices for the production of gold pens, and although a large number are manufactured in England, it is said that New York practically supplies the bulk of the gold pens used throughout the world.

By the courtesy and kindness of Mr. Evelyn De la Rue I have recently had the opportunity of seeing gold pens manufactured in the works in Bunhill-row. I have also been given valuable information on this subject by Mr. Watts, the London representative of the well-known firm, Messrs. Mabie, Todd and Co., of New York, and I propose using by way of illustration, some slides prepared from woodcuts with which Mr. Watts has been good enough to supply me. Without going into minute detail I would give a sketch of the various phases assumed during the process of manufacture:—

Ingot of Gold.—Beginning with the brick or ingot of pure gold, the first step, of course, is to alloy this with silver and copper to a fineness of 14 carats. The alloy is melted and remelted to ensure uniformity, and is then cast into ingot form. The ingots are then rolled into ribbons, of a width and thickness suitable for the particular kind, or size, of pen to be afterwards made from it.

Fly Press.—These ribbons are fed by hand into a fly press, the die and matrix of which, formed to the exact outline required, relentlessly cut or stamp out the "blanks" one after

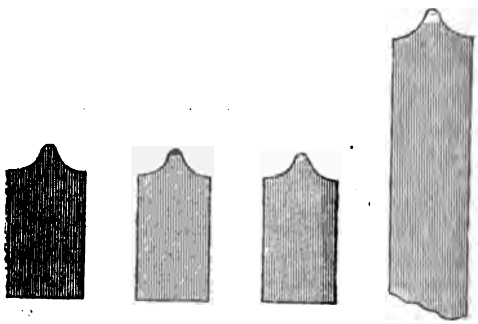
FIG. 48.



another as the operator swings the handle of the press, leaving the ribbon of gold as here shown, in Fig. 48. This is the birth of the gold pen, and its appearance coincides with the orifice formed in the ribbon.

Pen Blanks.—The "blank," as it is called, is shown in Fig. 49 at C. It is, of course, a flat piece of gold, and does not from its general form look like a promising writing implement, but it is ready to have its iridium point applied, and to this end the blank is first hollowed out on one side of the point as shown at D, to receive two carefully selected particles of the hard and costly iridium, which the workman,

FIG. 49.

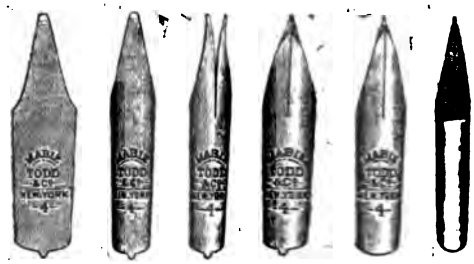


C D E F

by the aid of a strong magnifying glass, applies to the tip of the point. With a blowpipe flame the gold is fused around the iridium, and holds the grains firmly in place. This leaves the blank in the condition indicated at E, and is ready for the next process, which consists in passing it between rollers under a great pressure, which has the effect of elongating it considerably, as shown at F. The point is not touched, and the amount of rolling is regulated by the degree of elasticity required in the finished pen. Tempering is attained by the action of a steam-hammer, which also solidifies the gold and improves its elasticity.

Gold Nibs.—The blank is now cut a second time by means of punch and die, when it assumes more of the appearance of a finished pen, except that it is still flat, as at G. (Fig. 50). It also has embossed or stamped upon it the maker's name or some distinguishing device, and the point—which is still clumsy and thicker than the other part, as it has not been rolled—is carefully ground away with emery and oil until the iridium particles are exposed. The blank is now ready for raising or shaping into the curvilinear form shown at H, so familiar in pens, and this is done by a blow from a die of the correct shape, which presses the pen

FIG. 50.



G H I J K L

into form between its surface and that of a counter-die. Slitting is next accomplished by means of a thin disc of soft copper revolving at a very high speed, its periphery dipping into a reservoir of very fine emery and water and the action of this disc as a cutting tool is so positive that not even iridium can withstand it. The pen now, as seen at I, is not just the instrument one would select to write with. To reduce it to proper form, it is placed in a kind of holder, which firmly grips it right up to the root of the slit, and the sawn edges of the slit are carefully ground, polished on a thin iron disc revolving in oil and emery, and it requires all the skill of an experienced workman to make these edges exactly true and alike. This being done, as at J, K, the points are just as carefully ground, and the nibs are set in their familiar position. The setting must be properly done, as if one nib of the pen should be thicker or thinner than the other, or if one should not be an exact counterpart of the other, the pen will be useless. The last process is to roughen slightly the underside of the pen point, and thus enable it to hold the ink. This is done by the action

of the sand blast. The result of this is indicated at L, and his "nib-ship" is complete.

It may be of passing interest to state that, at the works of Messrs. De la Rue the workmen employed in making the gold pens are required to wash their hands and faces before leaving the premises, with the result that something like £150 to £200 worth of gold is recovered, per annum, and it is stated that in the works of the Waterman Pen Company, in the United States, a similar rule is enforced, producing about 90 dols. worth of gold each month. The clothing worn by the operators is the property of their employers, who burn the garments to ashes for the sake of the gold-dust they carry.

The gold nib has become the universal writing point of the fountain pen. The gold, as I have already stated, is used because of its non-liability to oxydise; and iridium is adopted because of its extreme hardness, which renders it peculiarly suitable to resist wear due to friction, as it glides over the surface of the paper. Gold pens may be had in every degree of flexibility, either with fine or broad point, and cut to any angle, so as to suit the requirements of the most fastidious, and the most exacting scribe.

Here I leave the subject till next week, when I intend to devote the whole of the time at my disposal to an account of the invention and perfecting of the Fountain Pen.

IRRIGATION IN EGYPT.*

Irrigation may be defined as the artificial application of water to the purposes of agriculture. It is, then, precisely the opposite of drainage, which is the artificial removal of water from lands which have become saturated, to the detriment of agriculture. A drain, like a river, goes on increasing as affluents join it. An irrigation channel goes on diminishing as water is drawn off it. Later on I shall show you how good irrigation should always be accompanied by drainage.

In lands where there is abundant rainfall, and where it falls at the right season of the year for the crop which it is intended to raise, there is evidently no need of irrigation. But it often happens that the soil and the climate are adapted for the cultivation of a more valuable crop than that which is actually raised, because the rain does not fall just when it is wanted, and there we must take to artificial measures.

In other lands there is so little rain that it is practically valueless for agriculture, and there are but two alternatives—irrigation or desert. It is in countries like these that irrigation has its highest triumph; nor are such lands always to be pitied or despised. The rainfall in Cairo is on an average 1·4 inch per annum, yet lands purely agricultural are sold in the neighbourhood as high as £150 an acre.

This denotes a fertility perhaps unequalled in the case of any cultivation depending on rain alone, and this in spite of the fact that the Egyptian cultivator is in many respects very backward. The explanation is not far to seek. All rivers in flood carry much more than water. Some carry alluvial matter. Some carry fine sand. Generally the deposit is a mixture of the two. I have never heard of any river that approached the Nile in the fertilising nature of the matter borne on its annual floods; with the result that the plains of Egypt have gone on through all ages, with the very minimum of help from foreign manures, yielding magnificent crops and never losing their fertility. Other rivers bring down little but barren sand, and any means of keeping it off the fields should be employed.

Irrigation in Egypt.—No lecture on irrigation would be complete without describing what has been done in Egypt. You are generally familiar with the shape of that famous little country. Egypt proper extends northwards from a point in the Nile about 780 miles above Cairo—a long valley, never eight miles wide, sometimes not half a mile. East and west of this lies a country broken into hills and valleys, wild crags, level stretches, but everywhere absolutely sterile, dry sand and rock, at such a level that the Nile flood has never reached it to cover its nakedness with fertile deposit. A few miles north of Cairo the river bifurcates, and its two branches flow each for about 130 miles to the sea. As you are probably aware, with rivers in a deltaic state the tendency is for the slope of the country to be away from the river, and not towards it. In the Nile Valley the river banks are higher than the more distant lands. From an early period, embankments were formed along each side of the river, high enough not to be topped by the highest flood. At right angles to these river embankments others were constructed, dividing the whole valley into a series of oblongs, surrounded on three sides by embankments, on the fourth by the desert heights. These oblong areas vary from about 50,000 to 3,000 acres. I have said the slope of the valley is away from the river. It is easy, then, when the Nile is low, to cut short deep canals in the river banks, which fill as the river rises and carry the precious mud-charged water into these great flats. There the water remains for a month or more, some three or four feet deep, depositing its mud, and then at the end of the flood it may either be run off direct into the receding river, or cuts may be made in the cross embankments and the water passed off one flat after another, and finally rejoin the river This takes place in November, when the river is rapidly falling. Whenever the flats are firm enough

* Extract from the Address of Sir C. Scott Moncrieff, K.C.S.I., K.C.M.G., President of the Engineering Section British Association at Johannesburg on August 28.

to allow a man to walk over them with a pair of bullocks, the mud is roughly turned over with a wooden plough, or even the branch of a tree, and wheat or barley is immediately sown. So soaked is the soil after the flood that the seed germinates, sprouts, and ripens in April without a drop of rain or any more irrigation, except what, perhaps, the owner may give from a shallow well dug in the field. In this manner was Egypt irrigated up to about a century ago. The high river banks which the flood could not cover were irrigated directly from the river, the water being raised as I have already described.

The Barrage.—With the last century, however, appeared a very striking figure in Egyptian history, Muhammed Ali Pasha, who came from Turkey a plain captain of infantry, and before many years had made himself master of the country, yielding only a very nominal respect to his suzerain lord, the Sultan, at Constantinople.

Muhammed Ali soon recognised that with this flood system of irrigation only one cereal crop was raised in the year, while with such a climate and such a soil, with a teeming population and with the markets of Europe so near, something far more valuable might be raised. Cotton and sugar-cane would fetch far higher prices; but they could only be grown at a season when the Nile is low, and they must be watered at all seasons. The water-surface at low Nile is about 25 feet below the flood-surface, or more than 20 feet below the level of the country. A canal, then, running 12 feet deep in the flood would have its bed 13 feet above the low-water surface. Muhammed Ali ordered the canals in Lower Egypt to be deepened; but this was an enormous labour, and as they were badly laid out and graded they became full of mud during the flood and required to be dug out afresh. Muhammed Ali was then advised to raise the water surface by erecting a dam (or, as the French called it, a barrage) across the apex of the delta, twelve miles north of Cairo, and the result was a very costly and imposing work, which it took long years and untold wealth to construct, and which was no sooner finished than it was condemned as useless.

Egyptian Irrigation since the English Occupation.—With the English occupation in 1883 came some English engineers from India, who, supported by the strong arm of Lord Cromer, soon changed the situation. The first object of their attention was the barrage at the head of the delta, which was made thoroughly sound in six years and capable of holding up 15 feet of water. Three great canals were taken from above it, from which a network of branches are taken, irrigating the province to the left of the western or Rosetta branch of the river, the two provinces between the branches, and the two to the right of the eastern, or Damietta branch.

In Upper Egypt, with one very important exception (the Ibrahimieh Canal, which is a perennial one), the early flood system of irrigation, yielding one crop a year, prevailed until very recently, but it was immensely improved after the British occupation by the addition of a great number of masonry head sluices, aqueducts, escape weirs, &c., on which some £800,000 was spent. With the completion of these works, and of a complete system of drainage, to be alluded to further on, it may be considered that the irrigation system of Egypt was put on a very satisfactory basis. There was not much more left to do, unless the volume of water at disposal could be increased.

Probably no large river in the world is so regular as the Nile in its periods of low supply and of flood. It rises steadily in June, July, and August. Then it begins to go down, at first rapidly, then slowly, till the following June. It is never a month before its time, never a month behind. It is subject to no exception floods from June to June. Where it enters Egypt the difference between maximum and minimum Nile is about 25 feet. If it rises $3\frac{1}{2}$ feet higher, the country is in danger of serious flooding. If its rise is 6 feet short of the average, there existed in former days a great risk that the floods would never cover the great flats of Upper Egypt, and thus the ground would remain as hard as stone, and sowing in November would be impossible. Fortunately the good work of the last twenty years very much diminishes this danger.

The Assuan Dam Reservoir.—In average years the volume of water flowing past Cairo in September is from thirty-five to forty times the volume in June. Far the greater part of this flood flows out to the sea useless. How to catch and store this supply for use the following May and June was a problem early pressed on the English engineers in Egypt.

During the time of the highest flood the Nile carries along with it an immense amount of alluvial matter, and when it was first proposed to store the flood-water the danger seemed to be that the reservoir would in a few years be filled with deposit, as those I have described in India. Fortunately it was found that after November the water was fairly clear, and that if a commencement were made even as late as that there would still be water enough capable of being stored to do enormous benefit to the irrigation.

A site for a great dam was discovered at Assuan, 600 miles south of Cairo, where a dyke of granite rock crosses the valley fo the river, occasioning what is known as the First Cataract. On this ridge of granite a stupendous work has now been created. A great wall of granite 6,400 feet long has been thrown across the valley, 23 feet thick at the crest, 82 feet at the base. Its height above the rock-bed of the river is 130 feet. This great wall or dam holds up a depth of 66 feet of water, which forms a lake of more than 100 miles in length up the Nile Valley, containing 38,000 million cubic feet of water.

The dam is pierced with 180 sluices, or openings, through which the whole Nile flood, about 360,000 cubic feet per second, is discharged. A flight of four locks, each 260 by 30 feet, allows of free navigation past the dam. The foundation-stone of this great work was laid in February 1899, and it was com-

pleted in less than four years. At the same time a very important dam of the pattern of the barrage north of Cairo was built across the Nile at Assiut, just below the head of the Ibrahimieh Canal, not with the object of storing water, but to enable a requisite supply at all times to be sent down that canal.

The chief use of the great Assuan reservoir is to enable perennial irrigation, such as exists in Lower Egypt, to be substituted in Upper Egypt for the basin system of watering the land only through the Nile flood; that is, to enable two crops to be grown instead of one every year, and to enable cotton and sugar-cane to take the place of wheat and barley. But a great deal more had to be done in order to obtain the full beneficial result of the work. About 450,000 acres of basin irrigation are now being adapted for perennial irrigation. Many new canals have had to be dug, others to be deepened. Many new masonry works have had to be built. It is probable the works will be finished in 1908. There will then have been spent on the great dam at Assuan, the minor one at Assiut, and the new canals of distribution in Upper Egypt, about six and a half millions sterling. For this sum the increase of land rental will be about £2,637,000, and its sale value will be increased by about £26,570,000.

INSANITY.

The Report of the Lunacy Commissioners just issued hardly supports the common opinion that insanity is largely on the increase in England and Wales. It is true that on the 1st of January, 1905, the ratio for the insane per 10,000 of population was 35·09 as against 34·71 for the same day of 1904, the actual numerical increase of the insane having increased from 117,199 to 119,829, say 2,630, or 2·2 per cent. But this is a lower increase than in any year since 1901, when it was only 1,333. In 1899 it was 3,114, in 1903, 3,251, and in 1904, 3,235. A striking fact brought out by the figures of the report is that during last year the increase of lunacy in rural districts was proportionately larger than in the towns. The Commissioners do not attempt to explain this phenomenon, and the specialists are not more courageous. The worry and stress of town life are not found in the same degree in the country, where existence pursues a more placid course, but intermarriage is more common in small villages than large towns, and conceivably may have something to do with the increase of insanity. Certain counties with a comparatively low rate of insanity show a high proportion of cases admitted with a history of intemperance, and others with a high insanity rate have a low rate of the latter class amongst the insane. For example, the admissions into asylums with history of previous intemperance coming from Glamorgan were 25·3 per cent., whilst the ratio of insane to 1,000 of the population was only 2·47 per thousand. On the other hand, in Dorset the admissions of persons with a record of intemperance was only 3·9; whereas the ratio of insane to 1,000 of population was 3·61. Nor is there any apparent relationship between the density of population and the ratio of insane. Many of the most sparsely populated counties give the highest proportion of insane to their respective populations. For example, the insane ratio was highest in Hertford (5·13), Radnor (4·98), Wilts (4·10), Cardigan (4·09), and Montgomery (3·93), counties which are amongst the least densely populated.

Turning to the assigned causes of insanity in the cases of all patients admitted into county and borough asylums, registered hospitals, naval and military hospitals, State asylums, and licensed houses in England and Wales during the five years 1899 to 1903, it will be found that the largest percentage, so far as males are concerned, is attributed to intemperance in drink, 22·7. The next highest percentage is under the head of hereditary influence, 18·8; then "previous attacks" 16·1. Mental anxiety and worry are answerable for 5·5, and adverse circumstances, much the same thing, for 5·6. Females differ considerably. With them the largest percentage, 24·9, was attributed to hereditary influence, then "previous attacks" 22·4, followed by "other bodily diseases or disorders" 13·1, intemperance in drink coming fourth with 9·4.

One of the most important portions of the report deals with the annual movement of the asylum population. The operation of Section 38 of the Lunacy Act, 1890, Sub-section 4 (as amended by Section 7 of the Act of 1891) has made it possible to judge the extent of this movement of the asylum population in general throughout a series of years. Under that section—a most valuable one—the reception order of any patient can only remain in force if continued by a special report by the responsible medical officer, made at stated periods from the date of admission, to the effect that the patient is still of unsound mind, and a proper person to be detained under care and treatment. Thus a patient admitted in 1891, if still retained in the asylum, must have had his reception order continued by this special certificate issued in 1892, 1893, 1895, 1898, and 1903. By means of such renewals it is possible to ascertain what proportion of the whole number admitted in 1891 and 1892 still remained under care during 1903 and 1904. The statistics show that for every 100 patients admitted in any given year not more than 48 will remain after one year, 37 after two years, 28 after four years, 21 after 7, and 15 after 12 years. It is not possible to give the actual numbers of those who were discharged recovered, or of those who died, nor, indeed, of those who had to be re-admitted, but in general terms it may be said that the highest proportion of recoveries is to be found in the first year, and of deaths in the later years. One-fourth of the admissions are for "not first" attacks of insanity.

HOME INDUSTRIES.

Drying Hops.—An interesting exhibit at the Brewers' Exhibition, held last week, was an American machine for drying and curing hops. With us the hops are kiln dried, the green hops being laid upon floors covered with horsehair, under which are enclosed or open stoves or furnaces. The heat from these is distributed as evenly as possible among the hops above by draughts below and round them. Exhaust fans are used by some growers, and greatly facilitate drying by drawing a large volume of air through the hops, and as the temperature may at the same time be kept low, the risk of getting over-dried samples is lessened. Then the adoption of the roller floor when used in conjunction with a raised platform for the men to stand on when turning, prevents any damage from the feet of the workmen, and reduces the loss of resin to a minimum. The principal objection to the English method, not entirely obviated by exhaust fans, is that hops are dried at too high a temperature, and not evenly. The hot air arising from the fire or furnace comes in contact with the hops lying next the hop-cloth and immediately absorbs moisture from the hops. As soon of this air becomes moisture-laden it is much heavier and cooler, and great heat is required to force the air up through the hops. The result is that the hops next the floor become overdried, while the hops on top remain cold and wet. The air-drying method referred to above dries the hops by a free and continuous passage of air through the hops. No heat is used, and the air is at the normal outside temperature. The circulation and draught are created by a large fan run by an electric motor. The drying is acccomplished by continuously renewed contact of fresh air with the hops. The moisture is absorbed and the brewing qualities left intact. The advantages claimed for the process are that (1) the process of drying begins immediately after the hops are picked, and there is no loss or damage from the sweating process. (2) The drying is accomplished easily and without heat, so that no hops can be high dried, neither will they be slack dried. (3) The hops are not handled in the process and no buds are broken. The resins are left in their natural state, namely, soft and soluble, and the aroma is uninjured. (4) The hops will present a uniform, clean appearance, rendering bleaching with sulphur unnecessary. (5) Being perfectly dried the hops will keep better in the bale as there will be no disturbing chemical changes. The process rests on theory that if you wish to dry any article you should expose it to the air not heat it. The washerwoman does not put her clothes on the oven to dry, she hangs them on the line. The air-drying process was invented, protected, and is used exclusively by a Californian Hop Company. Unfortunately it needs a Californian climate for its efficient application and this is not to be found in Kent.

Incandescent Gas and Electricity.—Something was said in this page last week about the growing keenness in the competition of incandescent gas and electricity as illustrated by the substitution of the former for the latter in the lighting of many of the streets in the City. Another indication of what the electric companies have to reckon with is to be found in the fact that the London and Brighton Railway Company's new station at Victoria is to be lighted by incandescent gas. In the old station it was substituted for electricity at a saving to the company, it is said, of £900 per annum. At Broad-street Station again the incandescent light is supplanting electricity, and Morland and Sons, of the City-road, have given up their electric plant, preferring high pressure gas. The gas companies, alarmed at the rapid progress of electricity, have for some little time past been bestirring themselves and offering householders facilities for the use of the incandescent light, and, if results are anything like those claimed for it, it is probable that the incandescent light will very seriously check the growth of electric lighting in residential houses as well as factories. If a saving of £900 a year can be effected in a single railway station by the substitution of incandescent gas for electricity, and a better light obtained, it is obvious that unless the electric companies materially reduce their charges their position will be seriously menaced. They are young and enterprising, with plenty of capital behind them, and may be relied upon not to shirk the fight, but in both house and street lighting they have found a formidable competitor in incandescent gas.

Motor Wagons.—The demand for motor wagons continues to increase, and for long distances they are steadily displacing the horse. They carry bigger loads, and there is a considerable saving in wages and other expenses. It may be interesting to give the particulars of working expenses of a five-ton motor lorry which was in constant use during twelve months ended September 30th last. It was at work 268 days, and travelled 5,562 miles at the total cost of £286 18s. 8d. The district in which it is worked is very hilly, and during all last winter the roads were in a very bad state, which necessitated a larger use of fuel than would otherwise have been used. The £286 18s. 8d. is made up as follows:—

Wages.

	£	s.	d.
Driver at 35s.	91	0	0
One man at 23s.	59	16	0
Repairs	63	14	5
Oil	22	6	11
Coke (57 tons 6 cwt.)	42	11	4
Boiler Insurance	2	10	0
Incidental expenses	5	0	0
	£286	18	8

5,562 miles × 5 tons = 27,810 ton miles for £286 18s. 8d., which works out at 2·47d. per ton mile, a substantial saving on horse haulage. Unfortunately soft roads prevent the general use of motor wagons for field work.

The Output of Coal.—The figures giving the output of coal for last year afford an amusing commentary on the report of the Coal Commission of 1866, which, by the way, was a very strong one. In their report, issued in 1871, the Commissioners stated that "as regards the future exportation of coal, although a very large increase has taken place within the period embraced by the preceding table (1855-69), yet there is reason to doubt whether much further increase will take place in this direction." The export given in the table for 1869 was 10,200,000. Add 2,100,000 for bunkers, and the total is 12,300,000. From the tables given in the Mines and Quarries General Report just issued, the total export of coal in 1904, exclusive of coke and patent fuel, was 65,822,035 tons, or considerably more than fivefold that which the Commission predicted would not show much further increase. On the other hand Jevons' prediction that the annual percentage of increase in the consumption of coal could not continue unabated for a very lengthy period is already being verified. Just forty years have passed since Jevons wrote, yet the increased production, which for some time previous had been at an average annual rate of 3½ per cent., has, notwithstanding the phenomenal development in the growth of our export, become reduced over the last twenty years to a geometric annual average rate of increase of about 2·16 per cent., and last year was less than 1 per cent., while the rate of increase in the *per capita* home consumption fell from 2½ per centum per annum in the fifties to less than three-quarters of 1 per cent. in the decade ended 1902. The consumption per head of population, 3·89, was lower in 1904 than in any year since 1899, and although the total output of coal was the highest hitherto recorded, viz., 232,428,272 tons, the value was only £83,851,784, as against £88,227,547 in 1903, when the output was less by more than 2,000,000 tons.

Other Minerals Raised.—The total value of the minerals raised in the United Kingdom in 1904 amounted to £97,477,639, a decrease of £4,330,765 as compared with 1903, and accounted for by a further fall in the average price of coal from 7s. 7·93d. per ton in 1903 to 7s. 2·58d. in 1904. The output of iron ore, 13,774,282 tons, shows a further increase of 8,637 tons, but the value, £3,125,814 is less by £104,123 then in 1903. The ore yielded 4,524,412 tons of iron or more than one-half of the total quantity of pig-iron made in the country. 6,100,756 tons of ore were imported during the year, 76 per cent. of which came from Spain.

Gold Mining in Great Britain.—The output of gold from Great Britain (confined to Merionethshire) does not increase very rapidly, but it seems to have made a considerable jump in 1904. In the Mines and Quarries General Report just issued (Cd. 2745) there are tables running back to 1873, of the quantity of ore extracted and its value. Up to 1900 the tonnage dealt with was quite insignificant, but in that year it rose to 20,802; in 1903 it was 28,600, and in 1904, 23,203. But whereas the 28,600 tons were valued (value meaning value of gold obtained less cost of treatment by crushing, amalgamation, &c.) at only £16,995, the 23,023 tons was valued at £68,576. No indication is given in the report of the explanation of this great difference in value. The whole of the output was obtained by two companies, the Gwyn Mines, Limited, working at Gwynfynydd, Merionethshire, and the St. David's Gold Mines, Limited, working at St. David's, Dolgelly. Altogether 19,655 oz. of gold were obtained by these two companies last year of a value, as stated above, of £73,925. The total cost of treatment is estimated to be about £5,349, but £68,576 does not indicate the shareholders' profit, because in order to make an estimate of the profit it would be necessary to deduct all the cost of getting the ore, *i.e.*, labour, supplies, superintendence, royalties, &c. It is to be feared that the nett profit of gold mining in Wales is still to seek.

State Afforestation.—Mr. Fel's proposal to grow forests in Great Britain has given rise to a good deal of interesting discussion. In other European countries the State has done much afforestation to the general advantage, as, for example, in the west of Jutland, where the land is singularly barren, and there can be no doubt that large areas in the United Kingdom might be profitably planted. But if it is to be done on the necessary scale it must be done by the Government. If the State were to take the work in hand it would be the means of finding employment for a large number of hands in one way or another, and the contraction of foreign sources of supply may soon induce statesmen to give more attention to the question of afforestation than they have been disposed to do hitherto, and persuade them to seriously grapple with the difficulties in the way. Meantime we are paying immense sums for foreign timber although less this year then for some years past. Indeed the decrease in the value of wood and timber imports for the nine months ended September last is somewhat remarkable.

Timber and Wood.—Taking wood hewn, the value of the imports for the nine months, which was £4,797,242 in 1903, and £4,395,246 in 1904, was only £4,162,341 in 1905, the decrease being mainly in Russian and American imports. The value of the sawn and split, plain and dressed woods has fallen from £13,278,683 in 1903, and £11,825,079 in 1904 to £11,218,169 this year, the decrease being mainly in Swedish, Norwegian, American, and Canadian imports, the last-named having fallen from £3,107,223 in 1903 to £2,401,219 this year. The total value of the wood and timber imported in the nine months to September 30th of 1903 was £19,919,175, in the same period of 1904, £18,256,364, and this year, £17,268,966; a decrease of no less than £2,650,209 for the nine months of 1905, as compared with the corresponding period of 1903.

GENERAL NOTES.

WHEAT IMPORTS.—Last year our largest imports of wheat came from the following countries in the order given:—(1) British India, (2) Russia, (3) Argentina, (4) the United States of America. For the nine months ended 30th September, 1905, the order has changed, and runs (1) Argentina, (2) British India, (3) Russia, (4) Australia. The United States, which in 1901 gave us 15·60 millions of quarters out of a total import of 23·46, comes fifth, sending us this year, in the nine months to September 30, only 3,606,300 cwt., as compared with 9,394,400 sent by Australia. And this is the more remarkable seeing that the wheat yield in the United States exceeds last year's by 23·7 per cwt., and is only 8·7 per cent. below the record year 1901. Canada, too, has a bumper crop of wheat, but the Canadian exports of wheat to the United Kingdom for the nine months ended September was only 3,020,630 cwt., as compared with 5,514,700 cwt. for the corresponding period of last year. It looks as if the home demand in Canada, as in the United States, is growing more rapidly than the increase in production. Take the wheat exports of the two countries for the first nine months of the three years, 1903-5:—

	United States. cwts.	Canada. cwts.
1903	18,999,026	8,134,441
1904	6,059 900	5,514,700
1905	3,606,300	3,020,630

On the other hand Russia sent us 10,302,702 cwt. in 1903 and 18,701,200 in 1905; the Argentine Republic, 12,989,155 cwt. in 1903, 20,574,800 in 1905; British India, 10,924,942 cwt. in 1903, 20,366,900 in 1905; Australia, 26 cwt. in 1903, and 9,394,400 in 1905.

FRENCH AND BRITISH COLONIAL TRADE.—Some figures given by Mr. Consul-General Inglis in his report on the foreign trade of France just issued (No. 5510, Annual Series), show that the trade of France with her colonies is much more valuable than is commonly supposed on this side of the channel. Taking imports and exports together, they were of the value, in 1904, of £41,792,000, the exports amounting to £22,300,000, and the imports to £19,492,000. Something more than half (£12,596,000) of the exports, go to and nearly a half (£9,352,000) of the imports come from Algeria, the colonies next in importance, from the trade point of view, being Tunis, French Indo-China, Senegal and West Africa, and St. Pierre and Miquelon. The figures quoted seem small beside those of Britain's trade with her colonies and India, but they are far ahead of those of any other country with her Colonial possessions. In 1903 our total imports from India and the colonies were valued at £137,178,061, and our exports at £128,571,535, in all £265,749,396. It is noteworthy that the imports of France from Great Britain in 1904 show a decline of £1,336,000, but remained larger than from any other country, whilst the increase in the exports from France to the United Kingdom amounted to £876,000. The effect of the recent war upon French trade with Russia was great. The imports from Russia fell from £12,068,000 in 1903, to £8,536,000 last year, and the exports to Russia from £3,376,000 to £1,696,000.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, OCT. 30...Farmers' Club, 5, Whitehall-court, S.W., 4 p.m. Mr. J. Crouch, "Rate-aided Education."

London Institution, Finsbury-circus, E.C., 5 p.m. Sir Robert Ball, "A Cruise with the Commissioners of Irish Lights."

TUESDAY, OCT. 31...The Faraday Society, in the Library of the Institution of Electrical Engineers, 92, Victoria-street, S.W., 8 p.m. 1. Discussion on paper by Prof. Ernest Wilson, "Alternate Current Electrolysis." 2. Mr. W. R. Cooper, "Alternate Current Electrolysis as shown by Oscillograph Record." 3. Prof. A. K. Huntingdon, "Note on the Crystalline Structure of Electro-deposited Copper." 4. Mr. W. Pollard Digby, "Some Observations Respecting the Relation of Stability to Electro-chemical Efficiency in Hypochlorite Production."

Central Chamber of Agriculture (at the HOUSE OF THE SOCIETY OF ARTS), John-street, Adelphi, 11 a.m.

WEDNESDAY, NOV. 1...United Service Institution, Whitehall, S.W., 3 p.m. Lt.-Col. G. M. Heath, "Field Engineering in the Light of Modern Warfare."

Royal Archæological Institution, 20, Hanover-square, W., 4 p.m. Mr. Alfred Dobrée, "Japanese Sword Blades."

THURSDAY, NOV. 2..Linnean, Burlington-house, W., 8 p.m. Rev. G. Henslow, "Plant Ecology, interpreted by direct response to the Conditions of Life."

London Institution, Finsbury-circus, E.C., 6 p.m. Mr. M. H. Spielmann, "Art and Humour."

Chemical, Burlington-house, W., 8½ p.m. 1. Messrs. E. Linder and H. Picton, "Solution and Pseudo Solution," Part IV. "Some of the Arsenious Properties of Arsenious Sulphide and Ferric Hydrate." 2. Mr. P. Blackman, "The Molecular Conductivity of Water." 3. Mr. H. O. Jones, "The Stereoisomerism of Substituted Ammonium Compounds." 4. Mr. J. E. Purvis, "The Influence of very strong Electro-Magnetic Fields on the Spark Spectra of Ruthenium, Rhodium, and Palladium." 5 Mr. E. C. R. Prideaux, "Note on the Fluorides of Solenium and Tellurium." 6. "The Constitution of Glutaconic Acid." 7. Messrs. H. Baron and J. F. Thorpe, "Some Alkyl Derivatives of Glutaconic Acid and of 2:6 Dioxypyridine." 8. Messrs. F. V. Darbishire and J. F. Thorpe, "Note on the Formation of β-methylglutaconic Acid and of αβ-dimethylglutaconic Acid."

FRIDAY, NOV. 3...Art Workers' Guild, Clifford's-inn Hall, Fleet-street, E.C., 8 p.m.

Geologists' Association, University College, W.C., 8 p.m. Conversazione.

No. 2,763. VOL. LIII.

FRIDAY, NOVEMBER 3, 1905.

NOTICES.

ARRANGEMENTS FOR THE SESSION.

The First Meeting of the One Hundred-and-Fifty-Second Session will be held on Wednesday Evening, the 14th of November, when an Address will be delivered by SIR OWEN ROBERTS, M.A., D.C.L., F.S.A., Vice-President and Chairman of the Council.

Previous to Christmas there will be Six Ordinary Meetings, one meeting of the Indian Section, and one of the Applied Art Section. The following arrangements have been made:—

ORDINARY MEETINGS.

Wednesday Evenings, at 8 o'clock:—

NOVEMBER 15.—Opening Address of the CHAIRMAN OF COUNCIL.

NOVEMBER 22.—"The Cinematograph and its Applications." By F. MARTIN-DUNCAN.

NOVEMBER 29. — "The British Association in South Africa." By SIR WILLIAM H. PREECE, K.C.B., F.R.S.

DECEMBER 6.—"The Manufacture of Sugar from British Grown Beet." By SIGMUND STEIN.

DECEMBER 13.—"Industrial Japan." By W. F. MITCHELL. HIS EXCELLENCY THE JAPANESE MINISTER, will preside.

DECEMBER 20.—"The Aerograph Method of Distributing Colour." By CHARLES L. BURDICK.

Papers for meetings after Christmas:—

"London Traffic." By CAPTAIN G. S. C. SWINTON (L.C.C.).

"The Preparation of Oxygen from Liquid Air." By MONSIEUR RAOUL PICTET.

"Submarine Signalling." By J. B. MILLET.

"The Supply of Electricity." By JAMES N. SHOOLBRED, B.A., M.Inst.C.E.

"The Planting of Waste Lands for Profit." By J. NISBET.

"Industrial Russia." By LUCIEN WOLF.

"The Horseless Carriage, 1885-1905." By CLAUDE JOHNSON.

"The Artistic in Painting and Photography." By J. C. DOLLMAN.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

December 7, January 18, February 15, March 15, April 26, May 24.

COLONIAL SECTION.

Tuesday afternoons, at 4.30 o'clock:—

February 6, March 6, April 3, May 1.

APPLIED ART SECTION.

Tuesday Evenings, at 8 o'clock:—

DECEMBER 12.—"Historical Pageants." By LOUIS N. PARKER.

December 12, January 30, February 20, March 20, April 24, May 15.

CANTOR LECTURES.

Monday evenings, at 8 o'clock:—

J. A. FLEMING, D.SC., F.R.S., "The Measurement of High Frequency Currents and Electric Waves." (In continuation of previous courses on "Electric Oscillations and Electric Waves," and on "Hertzian Wave Telegraphy.") Four Lectures.

November 27, December 4, 11, 18.

SIR WILLIAM WHITE, K.C.B., F.R.S., "The Modern Warship." Five Lectures.

January 29, February 5, 12, 19, 26.

PROF. VIVIAN B. LEWES, "Fire: Fire Risks and Fire Extinction." Four Lectures.

March 12, 19, 26, April 2.

ALFRED MASKELL, "Ivory." Three Lectures.

April 23, 30, May 7.

GEORGE W. EVE, "Heraldry in Relation to the Applied Arts." Three Lectures.

May 14, 21, 28.

HOWARD LECTURES.

A Course of Three Lectures will be given under the Howard Trust, by PROFESSOR SILVANUS THOMPSON, D.Sc., F.R.S., on "High Speed Electric Generators, with special reference to driving by Steam-turbines," on the followng Thursday Evenings, at 8 o'clock:—January 18th and 25th, and February 1st.

JUVENILE LECTURES.

Two lectures suitable for a Juvenile audience will be delivered on Wednesday evenings, January 3rd and 10th, 1906, at 7 o'clock, by PROFESSOR HERBERT JACKSON, on "Flame and Combustion."

CANTOR LECTURES.

Mr. Alan Cole's Cantor Lectures on "Some Aspects of Ancient and Modern Embroidery," and Mr. Herbert Laws Webb's Cantor Lectures on "Telephony," have been reprinted from the *Journal*, and the pamphlets (price one shilling each) can be obtained on application to the Secretary, Society of Arts, John-street, Adelphi, London, W.C.

A full list of the Cantor Lectures which have been published separately and are still on sale can be obtained on application to the Secretary.

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

RESERVOIR, FOUNTAIN, AND STYLOGRAPHIC PENS.

By JAMES P. MAGINNIS, A.M.Inst.C.E., M.Inst.Mech.E.

Lecture III.—Delivered February 6, 1905.

FOUNTAIN PENS.

I cannot do better than begin my lecture this evening by quoting the words of Mr. De la Rue, who says:—"As probably everybody knows, a fountain pen is a pen the holder of which contains a supply of ink which is made to flow to the nib by a device called the 'feed.'" It is the feed which is in great part responsible for the proper writing of the pen. When a filled pen is held point downwards, the ink it contains is acted on by a variety of forces, among which may be reckoned gravity, inertia, capillary attraction, air pressure, friction, and the viscosity of the liquid, as well as several minor forces. If the pen is properly made, these forces are in a state of equilibrium, and the ink does not run out of the reservoir. As soon, however, as the point touches a surface it is capable of wetting, the action of the capillary attraction is altered, with the result that the ink is enabled to flow from the reservoir, and that the pen writes. A fountain pen, to be perfect, should fulfil certain requirements. It should be of convenient form and size, and as light as possible. Its ink-carrying capacity should be as large as is consistent with its portability. It should not be too ready to empty itself, except when required to do so, and then only at a rate not exceeding the requirements of the writer. It should be prompt in delivering the ink the instant the nib touches the paper. It should have as few parts as possible, and these free from complication or liability to injury from careless handling. The possessor of such a pen, provided it be fitted with a gold nib suited to his style of writing, need not ask for a better. Many of those I shall refer to to-night are full of complications, and of what are now proved to be unnecessary parts, whilst others appear to be of the very essence of simplicity, perhaps too much so. Of fountain pens perhaps one may say, as of other things, the fittest survives, and in those of to-day will be found the adoption of the result of the experience of former days. *Experientia docet*. It is another case in which the principle of "trial and error" helps materially to assist one in arriving at the best means to an end.

Frederick Bartholomew Fölsch obtained a patent in 1809 (3235), for "Several Improvements calculated to promote Facility in Writing," wherein he describes his invention shown in Fig. 1, as being divided into three parts, namely, the box, B, the tube, T, and the socket, S, all of which may be joined together by screws, or socket joints. The socket, the lower part of which is made in the shape of a common pen with a slit up the nib, is hollow, and has a hole in the front to admit air, and to adjust the quantity of ink it will bear. At the lower end of the tube, T, is a small pipe, P, for the ink to pass through to the socket. The box, B, contains a small rod, R, one end of which passes through a hole in its bottom,

with a valve, V, covered with leather fastened to it, while the other end screws into a knob, K. A spiral spring, S, keeps the valve or plate close to the cotton of the box. Or, as shown in Fig. 2, the spring may be done away with by screwing the knob at once on to the tube, and making an airhole within the screw part of it, which will admit air into the tube by unscrewing the knob a little.

Again referring to the specification of Joseph Bramah, of September, 1809 (3260), we find that he there claims a patent for "A New Method of Making Pens, Pen-making Machines, Penholders, and Fountain Pens." In this specification, he describes how the handle of the penholder may be a hollow tube of silver or of any other metal or material proper for the purpose, tapering at the lower end to fit the socket, and with a small perforation a little distance from the point, the upper end being made airtight with a cork, cap, or otherwise. The tube is made so thin as to be readily compressed out of circular shape by a small pressure between the fingers and thumb which hold the pen. If a larger supply of ink be required than such a tube will hold at one time, a bulb may be added at the upper extremity or in any other part. Instead of a stopper, a piston may be slided down the interior of the tube to force down the ink to the pen, by the hand or screw, &c. Any common pen, Bramah says, may be converted into a fountain pen, by scraping that part of the quill where the thumb rests, until it is so thin that the pressure of the end of the thumb will be a little more than the necessary force for holding the pen, and by inserting into the open end of the pen above the mouth a small cork, or any substance calculated to operate as a stopper, having previously made in the part of this stopper which falls in contact with the back of the pen, above the slit, a small groove not larger in dimensions than the smallest pinhole, longitudinally along the surface thereof. Here we have a description of a very up-to-date fountain pen, with its feed bar very much as at present used.

In July, 1819, appeared the next patent (4389); granted to John Scheffer for a machine or instrument for writing, which he calls the "Penographic, or Writing Instrument." In this invention the ink is caused to flow to the nib by pressure exerted upon a lever. Generally speaking, the instrument consists of an external metal case, having at the top a stopper of cork, and near the bottom end a cock tube. Inside the case is an elastic tube formed of part of a goose quill, covered with sheep's gut. A valve or plug passing through the cock tube is acted upon by a lever. The nib is described as being formed of part of the barrel of a quill or other suitable material.

FIG. 1.

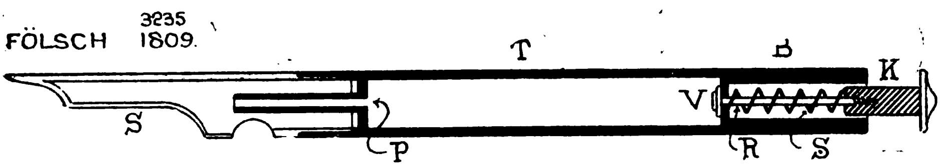

FIG. 2.

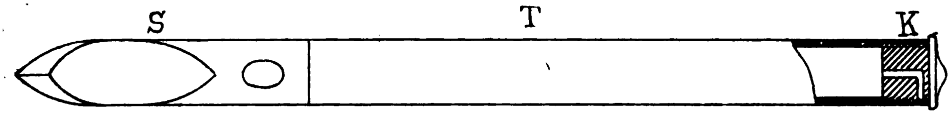

In December, 1819, James Henry Lewis, patented "an improvement on pens" (4426) which he calls, "Caligraphic Fountain Pens." This pen was made partly of a barrel of a quill and partly of metal tubes. Ink was caused to flow to the nib by pressure of the finger and thumb, and its flow was held in check by the insertion of a piece of sponge within the lower end of the barrel. The inventor also proposed making the barrel in duplicate, so as to hold different coloured inks, means being provided to supply the nib with either ink at will.

In July, 1827, George Poulton described "an instrument, machine, or apparatus for writing" (5517), which he calls a "Self-supplying Pen," composed of a "tube or reservoir, pen and shield," that may be

attached or separated at pleasure. The reservoir into which the ink is introduced, is screwed on to the pen. There is a weight within it which presses the ink into the pen by its own gravity when in use. The pen is made of steel, cased with metal, to prevent any corrosion, and is partly like a tube, with a valve within it to regulate the flow of ink.

John Joseph Parker obtained a patent (6288) in 1832, "for certain improvements in fountain pens," and he describes his pen (shown in Fig. 3) as having a piston, P, and rod in the barrel, B, with which to force ink to the nib as required, to which it is delivered through a small bell-mouthed tube, T. To fill the barrel, he says, dip the end of the penholder into ink, and raise the piston by turning the outer case. wound and fixed in the barrel of the nib, serving as an ink retainer. This is shown alongside, drawn to a larger scale.

Henry Columbus Hurry patented an improvement (107, 1852) whereby the ink was prevented from leaking out of the penholder when out of use, by the employment of a valve which was capable of closing the ink passage, and rendering the reservoir perfectly air-tight.

In 1852, W. R. Bertolacci describes (537) an "improved pneumatic ink and penholder." It consists, he states, of a tube or reservoir in which is inserted a tube of vulcanised india-rubber, if anything larger than the reservoir. The nib is inserted between these two tubes. The ink is made to flow underneath the nib. A pressure knob passing

FIG. 3.

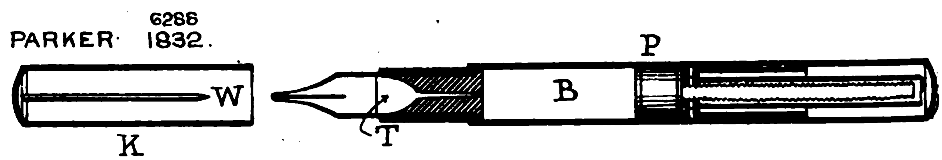

FIG. 4.

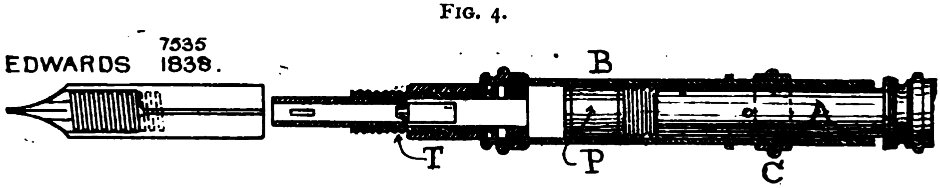

In this specification we have the first mention of a so-called, self-filling pen. A wire, W, attached to the inside of the cap, K, enters the ink-delivering passage, and prevents the outflow of ink when the cap is placed over the nib.

A telescopic penholder is shown in Fig. 4 (7535, John Edwards, 1838), formed of two tubes, A and B, each having an air-hole, the upper tube, A, sliding in the lower or ink reservoir, B, one end of the upper tube being packed to form an air-tight piston, P. An air-hole in the ink reservoir is covered by a sliding collar, C, on the outside, packed with leather, cork, or other suitable material to render it air-tight. The upper tube, A, when withdrawn, may be held in that position by turning it round two or three times, when it becomes screwed into the lower tube. A tapering plug, T, is provided in the ink duct, capable of adjustment to regulate the flow of ink to the nib. A wire is spirally

through the reservoir presses against the india-rubber tube. In the upper part of the tube or reservoir is a piston, which is moved up and down by a tube turning round with a screw, moving in the screw of the piston rod. To fill the reservoir with ink place the nib end in a vessel containing ink, and raise the piston by the screw. Methods of delivering ink to the nib are described, by means of elastic bulbs, on which pressure may be exerted as required. A cap is also referred to, which when screwed on the point of the pen renders it safe to carry in the pocket.

In 1855 a patent (410) was obtained by Newell A. Prince for an improvement in the ink feed. This inventor makes his fountain pen, as shown in Fig. 5, principally of hard vulcanised rubber. In the lower end of the reservoir, A, a feed tube is fitted, bored through its middle with a hole which is largest at its upper end. Near the bottom of the feeder an aperture is made, perpen-

dicular to the bore thereof, from which the ink issues to feed the nib. Within is a flat spring, S, whose upper end is wide enough to be wedged fast into the feeder, the rest being narrower than the diameter of the bore, so that it may vibrate freely by the action of the nib in writing. The lower end of the spring is bent nearly at right angles, to allow it to project through the aperture and come into contact with the under part of the nib. As the nib in writing is lifted from the orifice in the feeding tube, the end of the spring follows it, so that the constant motion of the nib when in use aids in supplying it with ink. The piston, P, and rod, R, furnish a ready means of filling the reservoir with ink.

A flat wire, provided with two thumb-plates, extends practically the entire length of the elastic tube, and openings are provided in the tubular part or casing of the pen through which the thumb-plates may be operated. Pressure on the thumb-plates will flatten the elastic ink reservoir, and if the point of the tube be dipped into ink, the expansion of the tube will be followed by a supply of ink. Or ink may be forced on to the nib by a slight pressure on the lower plate whilst writing.

Under the heading, "Fountain Pens," provisional protection was granted to John Butcher (1964), in July, 1870. The stem, he says, is an elastic tube closed at its upper end, and open at the lower end next the nib. To

FIG. 5.

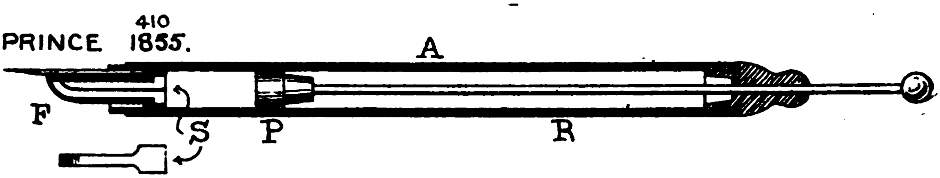

FIG. 6.

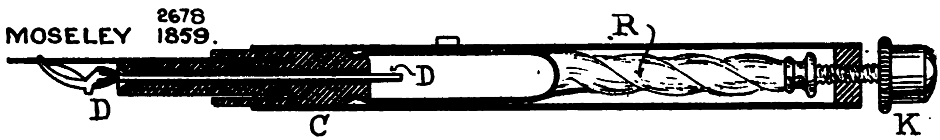

Walter Moseley's specification of 1859 (2678), describes a fountain pen (Fig. 6) in which the ink reservoir, R, is constructed of soft india-rubber, to fill which with ink, a screw cap, K, is turned a few times, whereby the india-rubber becomes twisted and forces the air out. On turning the screw the reverse way, and at the same time dipping the end of the penholder in ink, the india-rubber resumes its tubular form and draws up a supply of ink. To regulate the flow of ink to the nib, the part, D, may be adjusted in the plug, C. Pressure on the flexible tube (where it is exposed through an opening in the metal casing) will force ink downwards to the nib. The inventor sometimes provides a small knob or button for this purpose, as shown in the drawing, instead of leaving the india-rubber tube exposed.

In the invention of John Darling, in 1867 (288), the tubular part of the pen is, as the inventor states, completely filled (*i.e.*, from end to end) with an elastic tube, from which a distributing tube terminates under the nib.

charge the tube the air is expelled by twisting, drawing, or squeezing it; this being done, its resilience draws in the ink. The elasticity of the tube allows ink to flow to the nib for some time, and the supply is kept up by twisting or squeezing the tube. In combination with the tube are either two removable nibs, both of which, or only the under or writing one, are slit; or a piece of fibrous or porous material, to prevent too rapid a flow of ink to the nib.

Messrs. Rheinberg obtained provisional protection in November, 1870, (3002) for "Improvements in Penholders." No drawings are published with the specification, but we are told that the handle is tubular, and forms, with a flexible tube at its lower end, an ink reservoir. At one side of the handle there is a stud, on which "the finger presses in writing." This stud abuts on the flexible part, presses it inwards, and causes ink to flow out through a small hole in the bottom thereof into the pen. To charge the reservoir, the hole is immersed

in ink, and a piston which is contained in the hollow handle is drawn up.

In Stewart's patent of September, 1878 (3644), Fig. 7, an elastic tube, A, is protected by a barrel, B, of metal, or hard vulcanite, rendered somewhat flexible by suitable perforations. The head, E, or, as it usually called, the point section, is fixed in the barrel, and a slit, F, is provided in it for the reception of the nib, and a central duct, G, closed at its extreme end, through which ink is supplied to the under side of the nib. The pen may be filled by suction through the air opening at N. To prevent ink escaping when the pen is carried in the pocket, a cap or sleeve is provided, which may be turned one-half a revolution so as to cover the orifice supplying ink to the nib.

In November, 1878 (4714) S. Fox obtained provisional protection for a fountain pen. The penholder is tubular, and has attached to its upper end a length of flexible tubing of small diameter, the other end of which is connected to an ink bottle. To assist the flow of ink, the ink bottle is raised somewhat above the level of the writing table, preferably upon a stand the height of which might be adjusted to the most suitable elevation. The penholder terminates in a very small tube, fixed immediately under and against the nib, and being provided with a regulator whereby the flow of ink may be regulated. When not in actual use the pen is inserted in the ink bottle. This inventor further suggests that the ink bottle may be made to hook into the buttonhole, or be otherwise attached to the person.

The drawing, Fig. 8, shows a section of a penholder patented in June, 1879 (2261), by R. Spear. It consists of a holder and ink reservoir, A, to which the feeder of ink, B, to the nib, C, is joined. When the nib, C, is in position, the feeder, B, extends nearly to its point and almost touches its under side. A piston, F, with its rod, G, fits inside the reservoir, A, and is operated by the pin, H, slightly projecting through the holder, A, in which a slot is provided for its accommodation. The piston rod, F, is guided by a diaphragm, D, through which it passes. This diaphragm divides the ink reservoir from the upper half of the holder. To fill the reservoir the point of the holder is immersed in ink, and the piston drawn slowly upwards, when the ink is drawn into the holder.

F. W. Monck, in December, 1879 (4943), patented the method of regulating the supply of ink from the reservoir to the nib, shown in Fig. 9. The main reservoir is divided from the point by a wall or diaphragm, in which is a small opening, as shown at L. The pen-carrier, D, is pivoted at E, to a rod, M, carrying a valve, C, fitting the opening, L. The rocking action

Fig. 7.

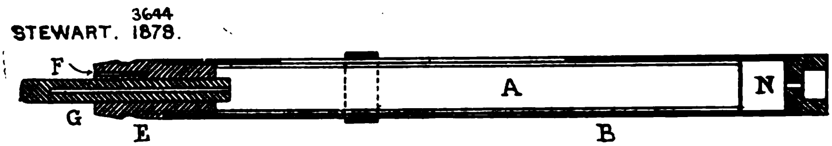

Fig. 8.

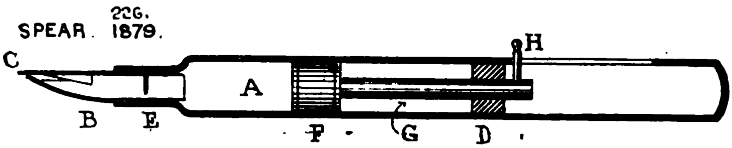

Fig. 9.

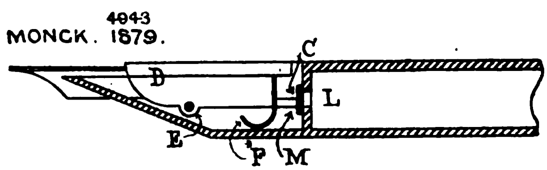

of the pen in writing opens the valve and allows ink to flow to the nib, whilst the spring, F, tends to keep the valve closed.

In July, 1880 (2879), Mr. A. T. Cross patented a pen, as he describes it, with a reservoir to which air is admitted at the lower end, and to be used with ordinary nibs. A section of the pen is here shown in Fig. 10, and compared with the fountain pen of to-day it is a complicated instrument, full of details which experience has proved to be superfluous. It has some

Another instance of a self-filling pen is referred to in the provisional patent of A. Tust, November, 1880 (4624), in which the ink reservoir is of the usual tubular form fitted with a piston and piston rod, which former also acts as a pressure valve to force the ink to the pen. The holder in which the nib is fixed is so arranged that it forms a valve to prevent too ready a flow of ink. Pressure upon the nib, as in writing, opens this valve.

Fig. 10.

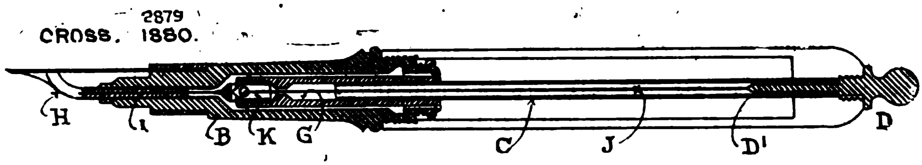

Fig. 11.

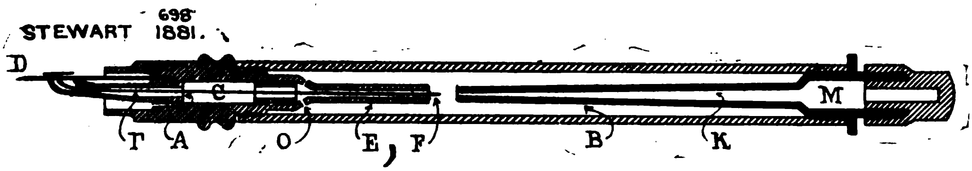

Fig. 12.

resemblance to the stylographic pen, and the inventor claims protection in the same specification for a stylographic pen having a somewhat similar interior arrangement of parts. In a fountain pen, the air tube, C, has at its lower end an adjustable sliding guide, G, to which a tube-clearing spindle, I, is rigidly fixed. The spindle, I, passes through a small ink-delivering tube, H, which is frictionally held in the bore of the point section, B. A fine connecting wire, J, attached to the guide, D', which extends from the vent plug, D, into an air tube, and passes through a contracted part of the guide, G, to which it is loosely secured, by its enlarged head being held in the chamber, K.

Stewart's patent of February, 1881 (698), consists of the usual ink reservoir, B (Fig. 11) within which is the air tube, K, enlarged at its upper end, M, and extending about two-thirds of the length of the ink reservoir. The point section is extended upwards, as at E, and openings, O, are provided, through which the ink finds its way downwards into the ink chamber, C, and thence by means of a short tube, A, to the nib, D. A capillary wire, F, is fitted to the top of E, and passes downwards to the nib, D, at the back of which it is formed into a coil, shown at G, to prevent the nib from becoming too dry when not in use. This wire forms a conductor for the air, entering in the form of minute bubbles, which gradually pass

upwards along its surface into the ink chamber, C, where they collect and form an elastic cushion between the ink contained in C, and that in the reservoir, B. This pen (also shown in Fig. 12) was introduced by Messrs. Mabie, Todd and Bard, of New York, as the "Calligraphic" Fountain Pen, and Mr. Robinson was the first to bring it to England.

Jackson's prov. patent 1881 (907), provides a flexible tubular reservoir of india-rubber, enclosed in an outer holder or casing. One end is attached to the lower end of the holder in which a passage is formed to carry the ink to the nib. The other or upper end terminates in a plug, turning which twists the flexible reservoir, and drives the contents, whether this be ink or air, outwards. To fill the reservoir the tube is untwisted whilst the point is inserted in ink.

is supported by a sleeve, and a small plunger or piston is placed against it so that pressure with the finger on this plunger compresses the rubber tube, and thus forces ink through a small opening immediately under the nib. The lower part of the reservoir is fitted with a plug terminating in a tubular feeder, with a small opening, through which passes a rod, said to be of some non-hygroscopic material to assist the flow of ink.

The ink reservoir of Sparling's pen of 1881 (3887), is closed at its lower end by a plug, perforated by a single hole, through which the ink passes to the nib. Into the other end a rod slides, packed so as to form an airtight piston by means of which ink may be drawn into the reservoir, or forced down to the nib.

In W. W. Stewart's patent pen of Feb-

Fig. 13.

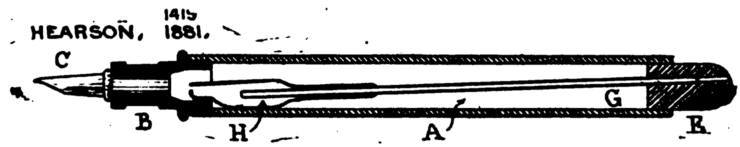

Fig. 14.

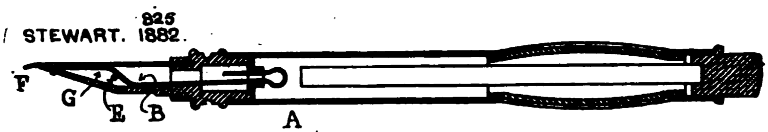

In T. R. Hearson's patent of March, 1881 (1419), Fig. 13, the reservoir, A, is fitted at its upper end with a plug, E, into which the air tube, G, is fixed. At the other end is fitted the nib holding piece, B, which is removable for filling the reservoir. The air tube, G, is inclined as shown, and is surrounded by an ink chamber, H, which serves to form a trap to prevent ink running into the air tube. The nib, C, is of the barrel type, and is surrounded by a thin india-rubber covering through which the points of the nib project slightly. The rear end of the nib is open to the ink reservoir, and the nib is kept fully charged with ink. As soon as pressure is brought to bear on the nib in writing, the points separate, and an ink passage is established which keeps the nib supplied. This immediately closes when pressure is relaxed.

In Poznanski's pen of 1881 (2754) at the top of the ink reservoir is fitted a soft rubber tube, one end of which is closed. This tube

ruary, 1882 (825), a section of which is shown in Fig. 14, in which a permeable strand, B, of cord or straw, or other suitable substance, is arranged to conduct the ink from the reservoir, A, to the nib, F. It is held in close contact with the nib by a pin, E. An ink tube or gutter, G, is formed under the nib. The interior of the reservoir is described as being glazed in order to attract globules of air, or glazed parts are introduced to effect the same purpose.

Cohn's pen of 1882 (840) was only provisionally protected, but shows the desire to produce a self-filling pen. The reservoir consists of an elastic tube closed at the top and communicating at the bottom with a small pipe, through which ink passes to the nib. To drive ink to the nib, and also to allow the tube to be filled by suction, the tube is compressed by means of a longitudinal block fitted in a slot in the penholder, and bearing against the flexible ink reservoir. In another form, a pin projecting through the

end of the penholder might be twisted, and with it the flexible tube.

Messrs. Hughes and Carwardine, in August, 1882 (4152), patented the method here illustrated in Fig. 15, of conducting ink to the nib by means of an india-rubber bag, B, through which the point, A, of the nib passes, as shown. Pressure upon the nib in writing causes the points to spread apart, thus expanding the opening in the rubber bag and allowing ink to exude. The rear end of the rubber bag is carried through the cylindrical part of the barrel of the pen, and turned thereover, as may be seen. In order to prevent ink from escaping at the point of the nib, the nib and bag are dipped in india-rubber solution.

FIG. 15.

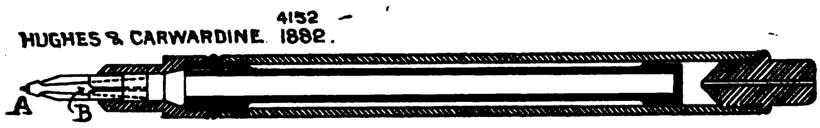

FIG. 16.

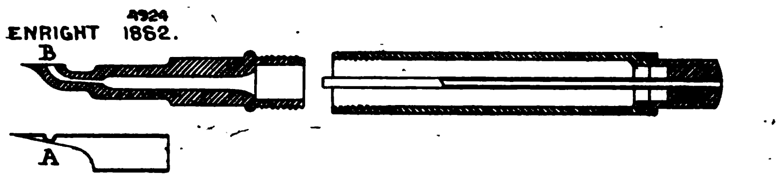

FIG. 17.

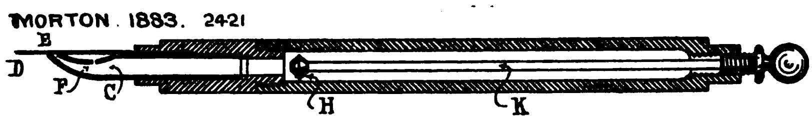

In Fig. 16 is shown the point section of a pen patented in October, 1882 (4924), by R. Enright. It will be seen that the ink passage takes an upward bend, and terminates immediately under the nib. The nib, illustrated separately underneath, is of barrel form, and has a distinct depression, A, which, when the nib is placed in position, completely closes the opening, B, of the ink passage in the manner of a valve. This valve would naturally open by pressure on the point of the nib in writing.

Robert Shaw, in October, 1883 (2411), used a tubular holder of metal or other material, entirely closed except at the lower end where the nib is entered, and at this opening, or a short distance therefrom, a cross or bridge piece is fitted in as support for the ink. Through the opening which admits the nib a number of very fine wires, hairs, or other minute fibres are passed, soldered, or otherwise fixed on the top of the holder, whilst their opposite ends lie against the under side of the nib, terminating within a short distance of its points. There is a small air-hole in the lower end of the holder. This, I think, is the first mention of air being admitted at the lower end.

In 1863 (2227) Joseph Maggs describes his invention of a fountain pen, in which the holder is hollow and contains a flexible tube of india-rubber, closed at its upper end, and connected with a short spiral tube which forms its mouth, at the other end. The spiral tube extends to near the point of the nib, and a slight pressure on the tube by the thumb or finger, in the act of writing ensures the requisite down-flow of ink. It is presumed (as there are no drawings published with the specification, which was only a provisional one), that there was an opening in the side of the metal holder to permit of the finger pressing upon the flexible reservoir. This is evidently a pen of the self-filling type.

In the patent of J. Morton, of July, 1883 (2421), shown in Fig. 17, a valve, H, is carried on a rod, K, which, at its upper end, is screwed into the end of the ink reservoir. When this rod is closely screwed down the

valve completely closes the ink passage, and thus prevents risk of leakage when the pen is lying flat, or carried in the pocket, point downwards. Ink is conveyed to the nib, D, when required, through the feed tube, C, to the vent, E. A small opening is also provided at F, to admit air.

Referring to Osborn's pen of 1882 (5558) a long pin passes through the ink reservoir, carrying two small valves, which regulate the supply of ink to the nib. These valves are normally held closed by springs. The nib is carried on a tube connected to the ink feeder. Pressure on the nib in writing opens both valves simultaneously, one admitting air, and the other allowing the flow of ink to the nib. ink is forced downwards. By untwisting the reservoir the ink is withdrawn from the nib. Provision is made whereby it is impossible to twist the flexible tube to destruction.

In Mr. J. F. Williams's invention (4505) of September, 1883. The reservoir consists of a tongue or tube, D, Fig. 18, capable of holding a considerable quantity of ink, and of delivering it at the underside of the nib, C, fitted in the usual manner into the tubular holder, A. The tongue, D, is carried on a rod, F. The upper end of this rod is fixed to a cap, E, which slides telescopically upon the holder, A, and which may be pressed forward against the spring, G. To fill the tongue, the cap, E, is compressed, and the tongue on being dipped

FIG. 18.

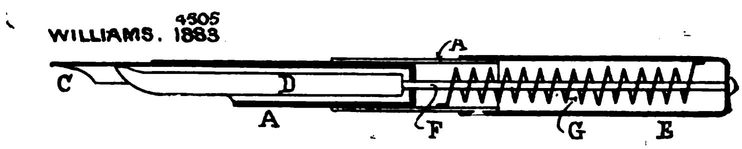

FIG. 19.

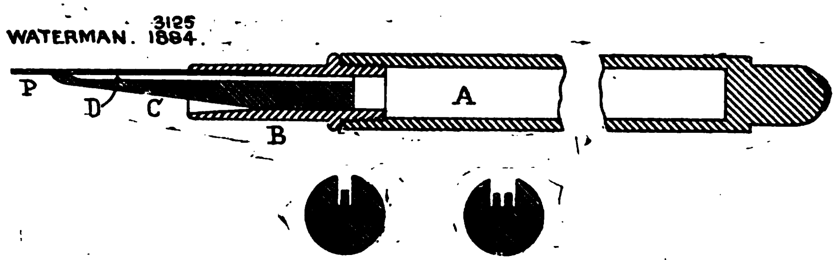


In Bertram's pen of 1883 (3268), the air tube (solid at its lower end), is fixed to the cap which screws on the end of the ink reservoir. The solid end of the air tube fits into, and closes the ink passage, through which the ink finds its way to the nib. When the cap is partially unscrewed air is permitted to enter the tube by an opening provided, and thence to the ink reservoir. The solid end is also thus raised from its seat, and ink is permitted to flow to the nib.

In Vale's pen of 1883 (4401) an elastic ink reservoir is contained within a protecting covering. The lower end of the reservoir is fixed to a mount, in which the nib is placed, and through this mount is a passage leading the ink to the under-side of the nib. The other end of the flexible reservoir is attached to a mount, controlled by a screwed cap. By turning the cap the reservoir is twisted, and

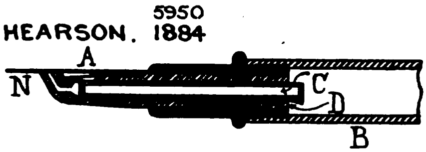
into ink becomes filled, and is then withdrawn to the position shown, by the action of the spring. This cannot be called a portable fountain pen. The inventor evidently intended to save frequent dipping into the ink-pot.

Fig. 19 shows the feed bar of L. E. Waterman, in 1884 (3125). The ink reservoir, A, carries a point section, B, at one end, and the feed piece, C, fits tightly into the point section. An ink duct, D, is formed along the feed, and consists of longitudinal fissures or saw cuts. The nib, P, is secured between the feed and the point section, and ink is fed to the nib by gravity and capillarity, air being drawn into the reservoir along the fissures of the ink duct. Below are transverse sections of the feed bar showing two arrangements of ducts. It will be seen that the main groove contains in one case two minor grooves, and in the other three, very fine saw cut grooves. These commence at the back

end, and extend nearly to the point as shown in the longitudinal section.

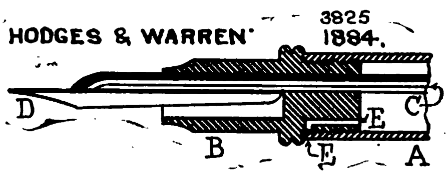
Mr. T. A. Hearson's pen of April, 1884, (5950), is illustrated in Fig. 20. In this drawing is shown a form of feed having two distinct passages, the upper one formed by the tube, C, conducts the air from the aperture, A, into

FIG. 20.



the ink reservoir, B, whilst the other passage, D, is formed by the tube, C, being flattened on its under side permitting the downward flow of ink to the nib, N. An arrangement not shown, is described, whereby ink may be prevented from passing along the channel, D, so that the pen may be safely carried in the pocket.

FIG. 21.



The feed arrangement of Hodges and Warren, of March, 1884 (3825), is shown in Fig. 21. In this pen a long tube, C, slit up its entire length, extends nearly to the top of the ink reservoir, A. The end of this tube is bent over at its lower end, and delivers the ink to the back of the nib, D, at the slit or pierce. An air hole, E, is provided to facilitate the escape of air while screwing the point section, B, into place in the reservoir.

Fig. 22 shows F. B. Michell's patent of September, 1884 (12092). Here the holder, F, contains a flexible rubber bag, C, from which the ink is expelled while writing by the pressure of the fingers, the holder, F, being slotted for this purpose. Ink is fed to the nib by means of the tube, A, and in the drawing it is shown as being delivered on the top of the nib. I possess a similar pen in which the ink feed is underneath the nib.

In Fig. 23, Köllisch's patent of 1884 (16800), the ink reservoir, A, is formed of a rubber tube from which the ink is ejected by twisting. The reservoir, A, is attached to the part, C, which carries a toothed ring, D, in gear with the outer casing, G, and also with the ring, F, attached to the cap, B. On turning the cap, and with it, D and C, the reservoir, A, becomes twisted. The teeth on G, prevent A from returning unless the cap be raised sufficiently to disengage the teeth which are kept in gear by means of the spring, E. As in other similar arrangements the reservoir is filled by allowing it to become untwisted whilst the point is immersed in ink.

In Brown's patent of 1886 (9132), the ink is distributed over the upper surface of the nib, by the feed bar, which is suitably formed for the purpose, and grooved to regulate the flow of ink. The air inlet consists of a tube, bent round at its inner end, so that the opening may face the plug through which the tube passes. A diaphragm is so pivoted as to be capable of entirely cutting off the ink from the nib.

In Bartram's pen of 1885 (10070), the ink is contained in the holder in the usual manner,

FIG. 22.

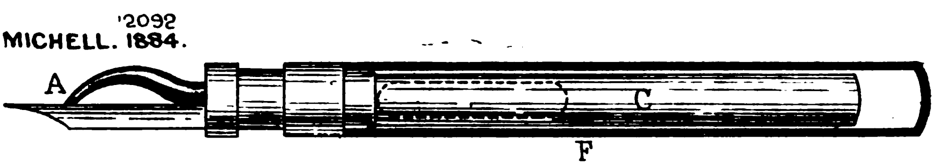


FIG. 23.

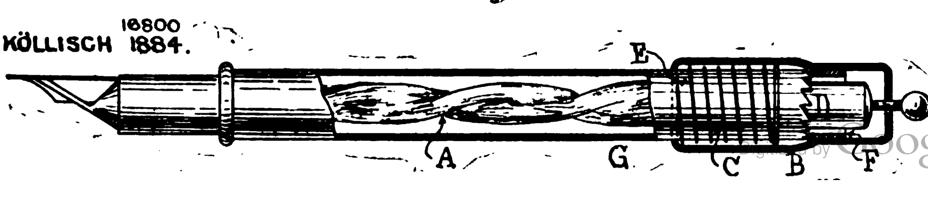

and flows to the nib, along a groove in the ink conductor. Entering this groove it is drawn downwards as the nib is moved in writing. An enlargement is formed in the conductor, having notches or serrations to permit of a free passage of air through the openings, in a diaphragm, into which latter, the ink conductor, or feed, is screwed. When it is desired to prevent ink from flowing, the conductor is screwed outwards till the opening is covered, in which condition the pen may be carried in the pocket. A rubber ring holds the ink conductor steady.

tains a reservoir, F, of india-rubber or other elastic material. This is attached at its upper end to a screwed rod, B, and a knob, A, by which it may be twisted to expel ink or air. A stud or pin, D, is placed at the side, and the reservoir, F, may be compressed by this means. Ink is delivered to the nib, N, through the passage, G, to C. The tongue, K, acts as a spring to grip the nib.

In Ridge's pen of 1886 (9346), shown in Fig. 26, the reservoir, B, is made of glass, drawn out at one end to a point through which a wick, C, projects against the nib, D. A

FIG. 24.

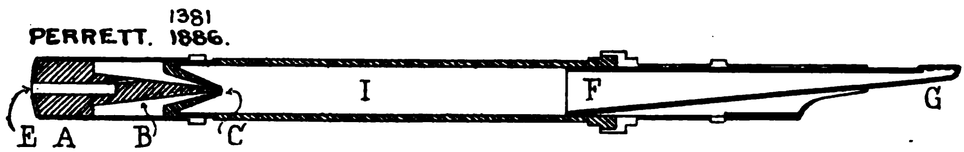

FIG. 25.

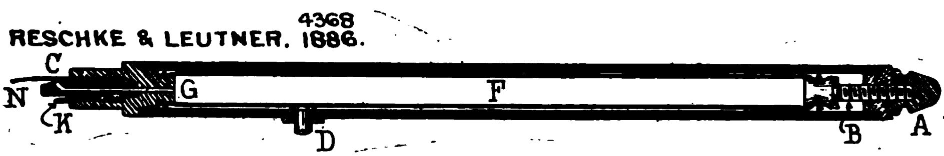

FIG. 26.

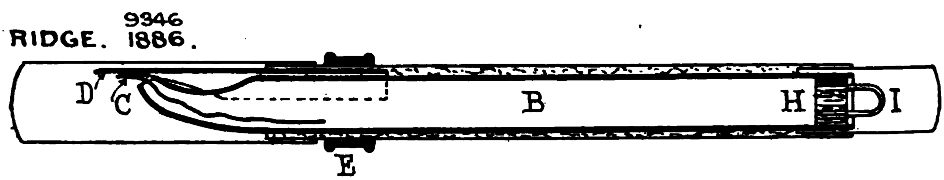

Fig. 24 shows a section of Perrett's pen of 1886 (1381). The tubular reservoir, I, is formed with an air-valve, C, and an ink conducting tube, F. The valve, as may be seen, is formed by a tapering point, B, attached to the cap, A, and by means of the latter, which has a screw connection with the reservoir, I, it may be raised or lowered as desired by turning the cap. Air is admitted at E, and when the valve is open, finds its way into the ink reservoir. The ink conducting tube, F. is of tapering form, and has a groove along which the ink flows to the spoon-shaped extremity, G. This is another instance in which air is admitted at the top of the fountain pen.

Another pen with a flexible rubber ink reservoir was patented by Reschke and Leutner, in 1886 (4368), and is shown in section in Fig. 25. The tubular holder or casing con-

movable plug, H, closes the upper end of the reservoir, and this is provided as shown with a wire loop, I. This plug may be pushed down the reservoir to the lower end, and raised to the position shown by a hooked rod, and thus the pen may be charged with ink. To protect the glass tube it is covered with an outer case, into which it is fitted by suitable packing. A sliding ring, E, is provided as a means of holding the nib in position.

Mr. G. H. Sackett's patent, August, 1886 (10827), shown in Fig. 27, an exaggerated barrel pen, made of metal, closed at its upper end and terminating at its lower end in a writing nib having an extra long slit. The lower end of the tube is closed also, so that any ink contained in it can only escape through the slit, to the point of the nib, and then only during the operation of writing.

In Sackett's patent of 1886 (12323), shown in Fig. 28, the tubular reservoir, A, is closed at one end, and provided at the other with a movable diaphragm, B, having a crescent-shaped slit for receiving the nib, C, and for allowing the proper flow of ink. A tongue, D, is attached so as to rest on the back of the nib, and a long feed bar or stem, grooved along its entire length, is attached to the back of the diaphragm, B. This feed bar is so bent that it may slide stiffly into the reservoir, thus enabling the holder to be refilled, without the necessity of entirely removing it. A minute opening in the diaphragm, B, admits air to the ink reservoir.

In the patent of Brown, of 1886 (15638), the inventor has turned his special attention to the feed arrangements, and the drawings shown in Fig. 29, give some idea of his various forms of feed bars. The inventor has a preference for an elliptical or triangular opening in the point

FIG. 27.

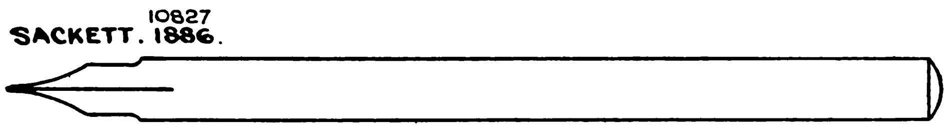

FIG. 28.

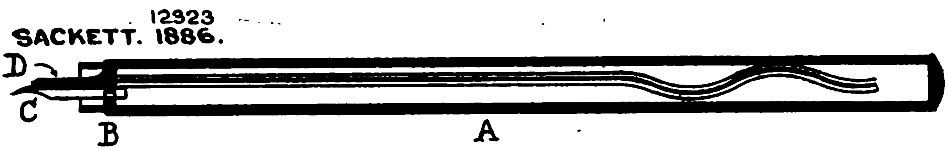

FIG. 29.

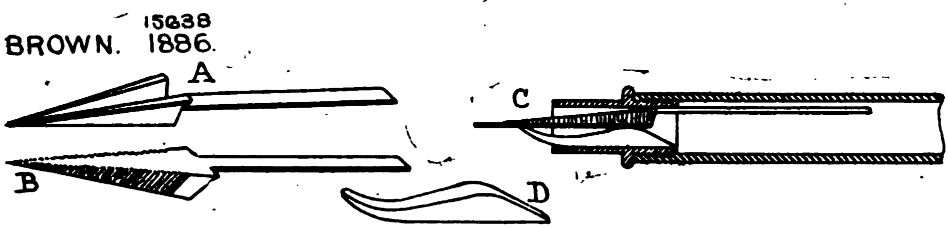

FIG. 30.

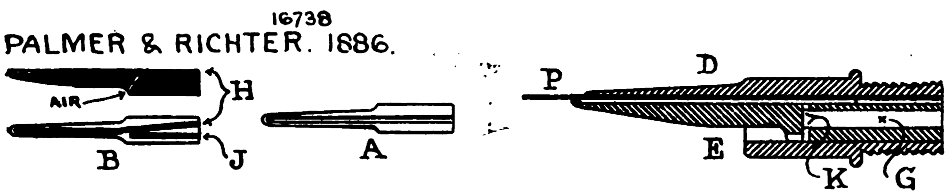

section, the feed bar itself being generally triangular in section, and more or less grooved to form air and ink ducts. In A the feed bar is pyramidal with a deep V-shaped groove, and a rearward extension. In B, it is grooved transversely. In either case the feed bar is placed over the nib, having an edge or apex in contact with it, as shown in C, the nib resting on the seating shown in D. The surface of this seating does not fit closely to the nib, in order that a void may exist to hold an additional supply of ink.

Palmer and Richter in their patent of 1886 (16738), claim improvements in feed bars. The reservoir is of ordinary construction. The point section is here shown in Fig. 30, provided with a beak, D, fitting over the nib, P. The feed bar, E, is hollow at G, with a channel extending the whole length of its upper surface which comes in contact with the nib, P. A channel is provided for the passage of the air which

FIG. 31

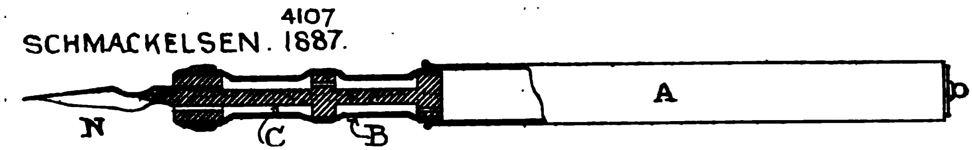

FIG. 32.

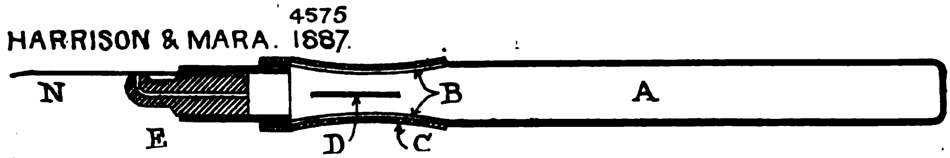
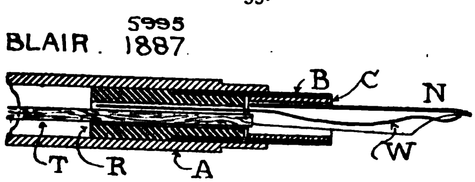


enters through openings at K, into the cavity, G. At A, is shown a plan of the feed bar, with the channel or groove along its upper surface. A modified form of feed bar is shown at B, the upper view being in section. In this, ink travels along the groove, H, to the nib, whilst air enters at the point indicated by the arrow, and passes along the shorter groove, J.

Fig. 31 is the invention of J. Schmackelsen in 1887 (4107). This is a combination of both rigid and flexible ink reservoir. The reservoir, A, is prolonged by the addition of a flexible tube, B, stiffened by a rod, C, provided with bosses supporting the flexible tube at intervals. Ink passages are formed in the bosses as shown. A ring at the end forms a termination to the flexible tube, and supports the front end of the rod, C, thus forming a holder to contain the nib, N. The rod, C, also carries ink to the nib. The flexible tube collapses, more or less, with the pressure of the fingers of the writer, and ink is thus forced forward.

Another flexible ink reservoir is here shown in Fig. 32, Harrison and Mara, 1887 (4575). The tubular holder, A, is of metal, and is provided with openings, B. These openings are covered with india rubber or some other elastic material, C, whilst the sides are stiffened by a partition, D. A section of the feed bar, E, shows the method of delivering ink to the nib, N.

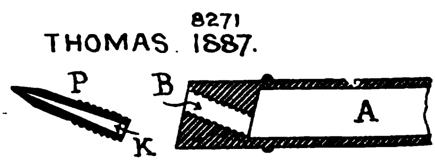
FIG. 33.



In Blair's pen of 1887 (5995), a part section of which is shown in Fig. 33, a corrugated tube, B, has a rubber tube, R, pushed in at the rear end to form a tight joint with the holder, A, and a second corrugated tube, C, inserted at the front end of the tube, B, provides a holder for the nib, N. The ink travels along the metal strip, which is held in position by the absorbent wooden rod, T. This rod, T, serves also to absorb any excess of ink in the passage when the pen is out of use.

In Fig. 34, W. J. Thomas, 1887 (8271), it will be seen that the reservoir, A, is perforated by an opening, B, at an inclination from the axis of the pen. Into this is screwed a short tube, P, through which

FIG. 34.



the ink flows to the nib. This tube has a tapering bore, as shown in the section at K, and a piece of cane is inserted therein. The nib is held in position by a bent plate, neither of which are shown on the drawing. The object in placing the feed tube at the angle shown is to prevent leakage when the pen is placed on a desk, and the holder is so weighted as to automatically keep the pen in the position indicated. Air is admitted at the top of the reservoir.

Again, in Fig. 35, is a flexible reservoir, patented by W. E. Burton, in August, 1887 (11728). A short rubber tube is fixed inside the outer protecting tube, A, and may be operated from the exterior by the stud and plate, B. Pressure on the stud compresses the flexible tube and forces a small quantity of ink to

the lower end of the pen, as shown, whilst air is admitted at V. On reversing the pen, the ink from the pen flows backwards to the chamber E.

The flexible ink reservoir is again shown in Fig. 36, patented by de Lambert in 1887 (15625). The tubes, A, B, form the reservoir. In B is a slot or opening, C, into which a small sponge is inserted, and a flexible rubber sleeve,

In the invention of G. H. Jones (7293), May 1888, the reservoir consists of a glass tube, drawn to a fine point at one end, and covered at the other after the manner of a drum with some elastic material, on pressing which ink is forced ont through the point to the nib. The reservoir is filled by heating the tube and then dipping the point in ink.

FIG. 35.

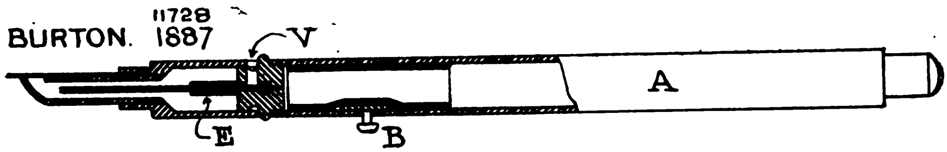


FIG. 36.

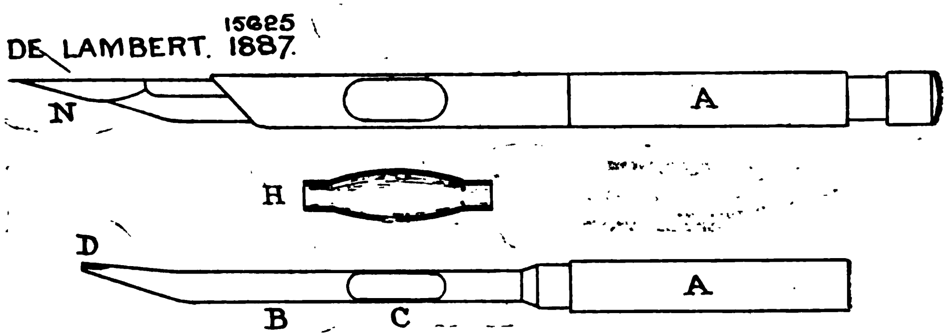
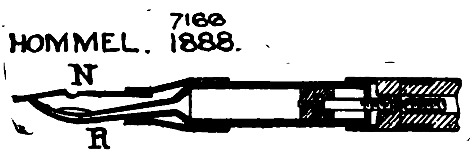


H, is slipped over this opening. Another metal tube is placed over this, as shown in the drawing of the complete pen, and this also has a slot or opening through which may be seen the rubber sleeve, H. Pressure with the finger upon the rubber sleeve forces ink through the opening at D to the nib, N.

In Fig. 37 we have Hommel's patent of 1888 (7166), being another instance of the introduction of a mechanical arrangement for draw-

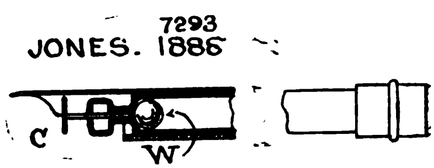
FIG. 37.



ing in or discharging ink by means of a piston, Ink is supplied through the fine tube, R, to the nib, N.

Fig. 38 shows a self-acting device by the same inventor for closing the ink outlet when

FIG. 38.



the pen is reversed. The disc, C, falls down upon the orifice; W is a weight provided to ensure its doing so.

There appears to be nothing particularly striking in this pen (W. Guthrie, 1888, 10934). In using the pen, it is first held with the point upwards, and then inverted, when a drop of of ink flows to the nib. When this is used the pen is again held point upwards, and so on.

In the invention of E. Lacon, in 1889 (8534), the reservoir is of glass or of other transparent

material, and the other protecting cover is slotted, so that the quantity of ink within may be readily seen. Fig. 39 shows the general appearance of the pen. A valve is provided for controlling the admission of air. A ring is placed on the upper end, capable of sliding up and down for the purpose of opening or closing the air inlet valve, V.

In Fry's patent of 1889 (10435), the reservoir is closed by a plug, and the feed bar is perforated by minute holes, so formed that the edges of the opening are in contact with the nib. For the purpose of regulating the flow of ink into the feed tube a plug is provided, into the reservoir for its entire length, as a means of forcing ink to the nib.

Falconnet and others took out a patent in 1889 (7784), for a piston type of pen, the ink being expelled from the reservoir by the movement of the piston. The piston has a threaded perforation, through which passes a rod, the rear end of which is secured to a cap, and as the cap is turned, so the rod is also turned, and by reason of the screw the piston is thus made to traverse the interior of the reservoir. The ink flows to the nib through a tapering tube or feed bar which is slotted under the nib

FIG. 39.

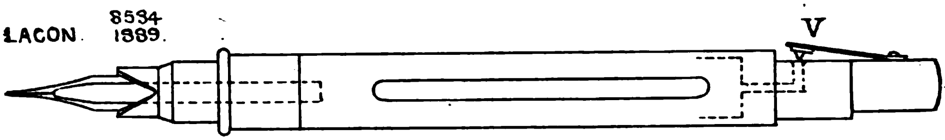


FIG. 40.

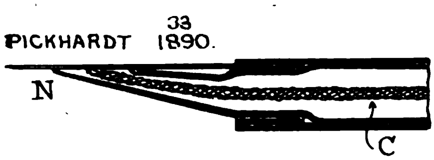

FIG. 41.

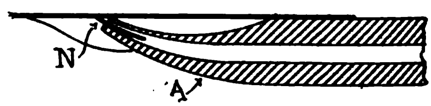

FIG. 42.

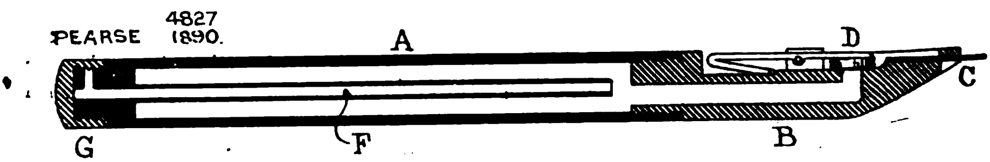


which may be screwed down to close completely the passage to the feed tube. When unscrewed the ink flows through the orifice.

Fig. 40 shows Pickhart's pen of 1890 (33), the reservoir of which is made of glass drawn to a fine point. Within the tapering point is placed a tube C, of gauze or woven asbestos, the end of which is in contact with the under side of the nib, N. A modification is shown in Fig. 41, where the point or feed tube, A, is of vulcanite, and, instead of the gauze tube, C, of Fig. 40, a tongue is cut from the nib, N, which is in contact with, or just enters, the ink outlet.

H. Pearse designed a pen in 1890 (59), which instead of having the familiar piston and its rod is fitted with a plunger screwing

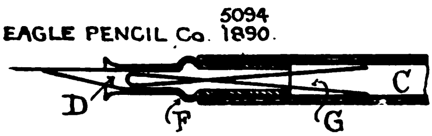
In the invention (3252) of Hill and Appleton, 1890, the reservoir is of gutta percha (placed within a metal tube), and is open at one end, and closed at the other. Into the open end is screwed the feed bar, which is hollow, and has two small openings for the admission of air, and out-flow of ink to the nib placed immediately over them.

In Fig. 42 Pearse's patent of 1890 (4827), the nib, C, is carried on a part, B, screwing into the reservoir, A. The outflow of ink is regulated by a valve, D, operated by a lever as required. Air is admitted at the other end of the pen through a tube, F, which is covered by the cap, G, when out of use.

This pen, Fig. 43, the production of the Eagle Pencil Company, 1890 (5094), is described

as being formed in three parts, the reservoir, the barrel, and the feed tube. The reservoir, C, is connected to the barrel by an elastic tube, F. The feed tube is formed with a swelling or shoulder, which prevents it slip-

FIG. 43.

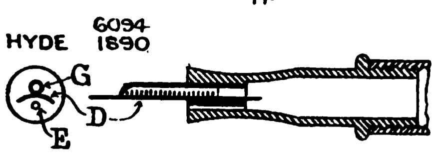


ping too far forward, and it is slotted for the ink to flow to the nib. A folded wire, G, passes from the feed tube to the reservoir.

The Eagle Pencil Company, in 1890 (15053), describe a pen in which the nib is held between the barrel and the ink conductor. At the rear end of the barrel is an india-rubber tube connecting it to the reservoir. The ink conductor or feed bar has one or more longitudinal grooves, and a saw-cut under the point renders it more flexible.

In Hyde's patent of 1890 (6094) the feed tube is cut with a number of transverse slits to render it flexible. Fig. 44 shows a longitudinal section of the nib socket, which is

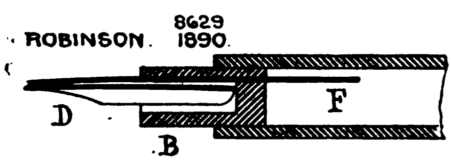
FIG. 44.



formed with openings for the nib, D (as shown in cross section). A feed tube, G, and an opening, E, for the admission of air. A longitudinal slit is provided immediately over the nib for the delivery of ink.

The reservoir in Robinson's patent of 1890 (8629), shown in Fig. 45, is provided with a plug, B, adapted to hold the nib, D. This

FIG. 45.



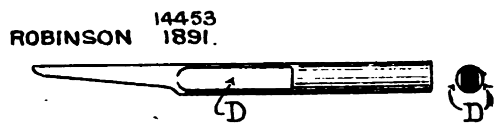
plug is provided with a groove above the nib, and in which is placed a wire or strip, F, flattened at the end in contact with the nib. A filling piece is placed in the groove, so that ink flows only in the narrow space between the wire and the surrounding walls.

In Shaw's patent of 1891 (6398), the reservoir is closed at one end, and has two openings at the other for the inlet of air, and for the outlet of ink, respectively. The lower, or penholder part, screws on the reservoir, and has openings corresponding to the inlet and outlet openings. It is hollowed out to receive the nib part. The nib is covered with a plate, between which and the nib the ink flows, air entering at an opening provided.

In theinvention of Krulis and Adutt of 1891 (3523), the ink is contained in the reservoir, and flows to the nib through a tube. This tube may be carried by the valve carried on a rod fixed to a plug fitted in the upper end of the reservoir. An elastic rubber plug or spring forces the plug outwards, and thus keeps the valve normally closed.

Mr. Robinson (1891, 14453) has here designed a feed bar of solid construction, formed with two flattened surfaces as shown in Fig. 46, at D, one on either side, to allow of the passage of ink from

FIG. 46



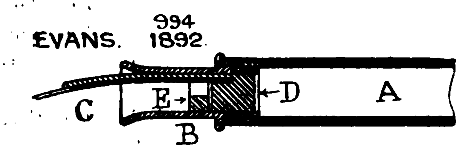
reservoir to the nib. Mrs. Robinson has to-day kindly handed me a pen which Messrs. Harmsworth produced under the name of "Answers" pen, and the feed bar now shown appears to be identical with that of this pen. It is interesting to note that the "Answers" pen was designed by Mr. Robinson in response to Messrs. Harmsworth's offer of a five-guinea prize for the best new invention, and he was successful in winning the prize.

Another pen is the invention of A. Theodorides in 1891 (17053). In this case the reservoir consists of an india-rubber bag closed at one end, and having a rigid bent nozzle at the other, so adapted as to be in contact with the underside of the nib. In the outer case is an aperture through which the reservoir may be compressed by the finger when the nib requires a fresh supply of ink.

The feed bar shown in Fig. 47, T. W. Evans, 1892 (994), is of simple construction. A the ordinary reservoir, having a point section, B, screwed into it. A nib, C, of ordinary form, is held in grooves in the point section,

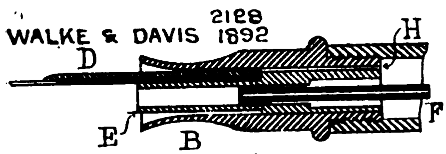
and further kept in place by the plug, E. The solid plug, D, with its projecting beak or tongue, serves as a feeder for the ink from the reservoir to the nib, small passages (not shown on the drawing) being formed at its side for the purpose.

FIG. 47.



In Fig. 48, 1892 (2128) is shown the feed arrangement of Walke and Davis. Air tubes, E and F, are fitted within the point section, B. The tube, E, is wide at the upper part to fit the bore, B, and of less diameter at the lower part to receive the nib and ink conductor, D. A

FIG. 48.



groove, H, is formed in the tube, E, to allow ink to flow to the conductor. Within the tube E, is fitted the adjustable tube, F, having a small bore for the gradual admission of air to the reservoir.

A piston of peculiar construction is used in the pen shown in Fig. 49 (3325, Blake, Pratt and Taylor, 1892). It is formed of a tube, B, having a longitudinal slit or saw cut, and filled with india rubber to render it elastic and form a tightly-fitting joint. Attached to the piston is a casing, G, which slides with the piston. The feed tube, C, is fitted with a valve, V, to regulate the ink flow, and with a mid-feather, F, to feed the ink to the nib.

In Fig. 50, L. Lowenstein, 1892 (17393), the tube, A, is formed with internal screw threads at each end. In the lower end two plugs, B and C, are screwed. One plug B has two holes, and a conical projecting portion, E, which enters the opening in the plug, C. The position of the lower plug, C, can be altered by means of a milled head, O, and the amount of opening thereby regulated. Ink flows to the nib, N, through a passage provided. An air inlet is arranged at the upper end of the reservoir, so that when the cap, T, is slightly unscrewed air may enter through the channels formed in the plug, P. To fill the pen with ink, the plug, P, is removed.

In the invention of W. Higgs, patented in December, 1892 (23632), the ink reservoir consists of a rubber bag contained in the body of the pen, and attached at its mouth to a cylindrical piece, and at the other end to a revolving plug. The pen is filled by twisting the plug, and with it the rubber tube, so as to expel the air. On immersing the point in ink and reversing the twisting action, ink is drawn into the reservoir.

In Fig. 51, Leary and Callahan, 1893 (13092), A, is the usual ink reservoir, and B, is the point section, having a nib holding section, C. The nib passes through the hole, and is attached to the spiral spring shown coiled within, B, the end of which passes upwards through an opening in the butt end of the nib, and then passes down its back, reaching to the slit. When the cap, D, is placed over the point, the nib impinges upon the swivelling

FIG. 49.

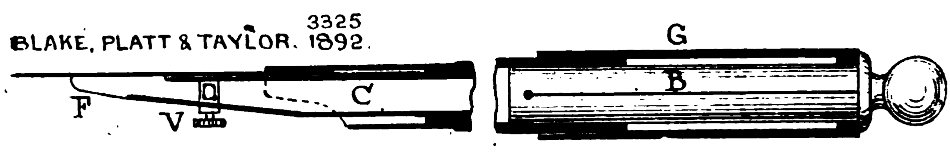


FIG. 50.

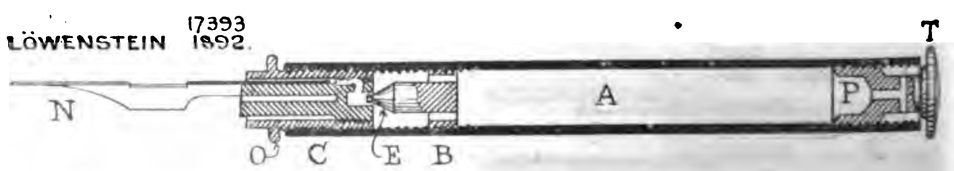

FIG. 51.

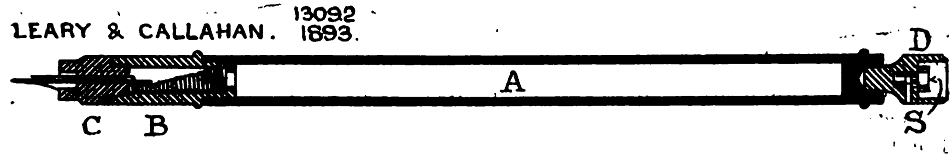

FIG. 52.

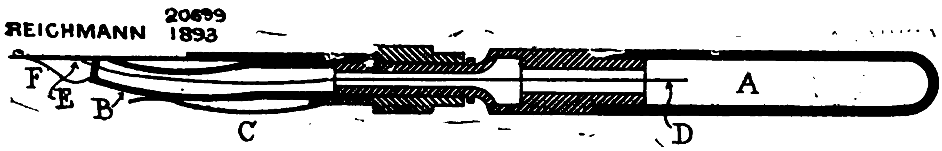

FIG. 53.

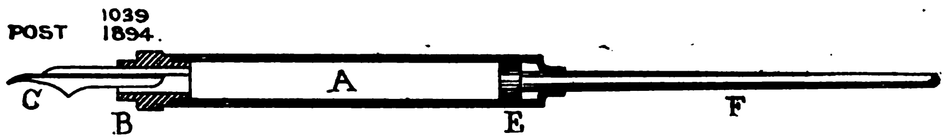


part, S, and is forced backwards against the pressure of the feed spring, which projects the nib into the forward position when the cap is again removed.

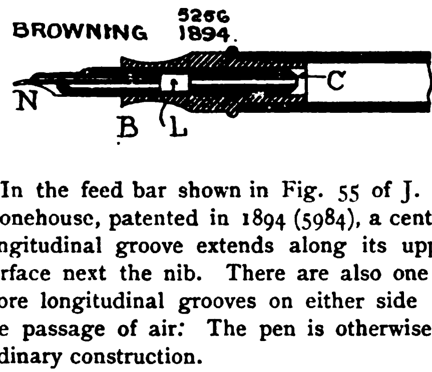
J. E. Chase, in 1893, patented a pen in which the nib is permanently attached to a rod by a rivet. The chief feature of this pen lies in the arrangement whereby the nib is made to recede when out of use.

The pen shown in Fig. 52, E. Reichmann, 1893 (20699), the inventor states, is for use with any form of steel nib. The reservoir, A, communicates with the flexible tube, B, which is pressed against the nib, F, by means of the spring, C. A wire, D, extends from the reservoir, A, through the tube, B, and terminates at E, and thus conveys ink to the nib, F.

The body, A, of the pen shown in Fig. 53 W. Post, 1894 (1039), contains a plunger or piston, E, attached to a rod or handle, F. The nib, C, fits into grooves in the point section, B. The body, or reservoir, A, is filled with ink by operating the plunger, E. The original pen as described in the patent specification, shows the rod, F, as one piece, but the pen as now made has a telescopic rod, which reduces the length of the complete pen.

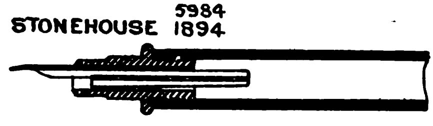
Fig. 54 shows a section through the ink feeding arrangement of C. E. Browning, 1894 (5256). The feed bar, C, is formed in one piece, and fits into the nozzle or point section, B. The nib, N, is held between the upper and lower tongues as shown, and projects backwards into the ink chamber, L, which communicates with the ink reservoir by the side ducts. Grooves on the inner surfaces of the tongues communicate with the air passage, which runs centrally through the feed bar. This pen was introduced by Mr. Robinson as the "Regal."

FIG. 54.



In the feed bar shown in Fig. 55 of J. H. Stonehouse, patented in 1894 (5984), a central longitudinal groove extends along its upper surface next the nib. There are also one or more longitudinal grooves on either side for the passage of air. The pen is otherwise of ordinary construction.

FIG. 55.



The invention, D. Arriaza, 1894 (9220), illustrated in Fig 56, relates to a pen in which a solution of solid ink is used to write with. The pellets of ink are stored in the receptacle, B. One or more of these pellets are placed in the reservoir, A, into which water is introduced.

The internal reservoir G, is of flexible rubber tubing, and by exerting a slight pressure on the stud F, ink is forced along the tubes, D, and an ink conductor to the nib, H. When the pen is out of use the cap, E, is pushed backwards so as to cover the opening in the feed tube, D,

The feed bar, F. C. Brown, 1894 (10838),

FIG. 56.

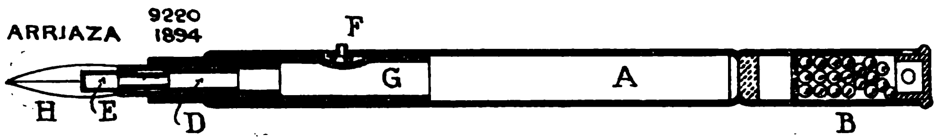


FIG. 57.

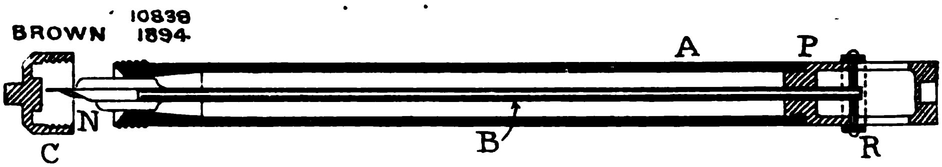
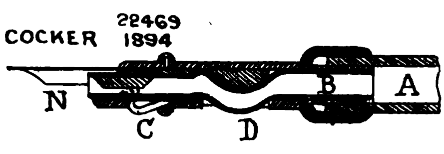


in Fig. 57, carries the nib N, between two tongues, and it extends rearwards in the form of a rod, B, through the plug, P, which is screwed into the other end of the ink reservoir, A. When the pen is out of use the nib is drawn into the nozzle of the reservoir by means of the sliding ring, R, attached to the rod, B. The cap, C, is then screwed on the front end, forming an air-tight joint, and preventing leakage of ink when carried in the pocket.

In Fig. 58, F. S. Cocker, 1894 (22469), shows another adaptation of the flexible reservoir to force the ink to the nib. It will be seen that the flexible tube, B, extends from the lower end of the ink reservoir, A, to the feed bar, a short portion of it projecting on the underside of the penholder. By pressing this portion, D, ink is

FIG. 58.

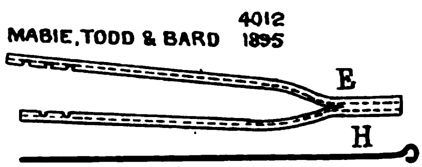


expelled to the nib, N. When the pen is out of use, a cap is pushed over the nib and front end of the penholder, forcing a bent piece, C, upwards, thus closing the ink outlet.

As everyone knows, Fig. 59 is a drawing of the feed bar of the well-known "Swan" Fountain Pen (1895, 4012, Mabie, Todd, and Bard), patented ten years ago. A flexible tube, E, is split for the greater portion of its length, and the legs bowed apart as shown. Notches are provided at the end of each leg. The nib is held between the two legs. The grooves in the legs which originally formed the bore of the tube, E, serve to carry ink to the nib and air to the ink reservoir, assisted by the bright surface of the wire, H, running through the bore of the tube.

A patent was granted in April, 1895, to J. Glass (7199), for a fountain penholder having a

FIG. 59.



flexible rubber ink reservoir, terminating in a tubular glass ink feeder. By pressing the flexible reservoir on the surface visible through the opening in the outer protecting casing, ink is made to flow to the nib.

The nozzle or point section, B, in Fig. 60. W. W. Stewart, 1895 (13566), is screwed into the ink barrel, or reservoir, A. The thickened end of a stopper bar, F, fits into the end of the nozzle eccentrically, leaving a crescent-shaped opening into which the nib, C, is inserted, and held firmly by the top feed bar, D. Ink flows down to the nib and through openings around it as shown. The stopper bar, F, is hollow and slit longitudinally to establish ink communication between the nib and the reservoir. The bore of the bar, E, is partly filled by a wire, F, having a spherical knob on its outer end, by means of which the feed may be adjusted.

In Fig. 61, H. Brams, 1896 (1029), the ink is contained in the flexible rubber bag or reservoir, C, and supplied to the nib through the upturned opening, D. An outer metal case protects the reservoir, and has an opening at F, whilst a plate, E, extends all along the parallel portion of C, between it and the cover. The cap is formed with a blunt point which when inserted in the hole, F, forces the plate, E, against the reservoir, C, thus compressing it. On its release a supply of ink may be drawn into the reservoir.

along a spiral groove to the neck, and thence along other grooves filling pockets, which are connected in pairs by holes, and it finally passes along the feeder to the nib.

Fig. 62, W. Schlomberg, 1896 (25441), shows yet another piston-action pen. The reservoir is filled with ink by withdrawing the hollow tubular plunger, C, the point, G, having been immersed in ink. On covering the outlet, G, and opening the air inlet, I, the plunger may be pushed into the barrel, A. The ink guide, H, is then replaced in the orifice, G, as shown

FIG. 60.

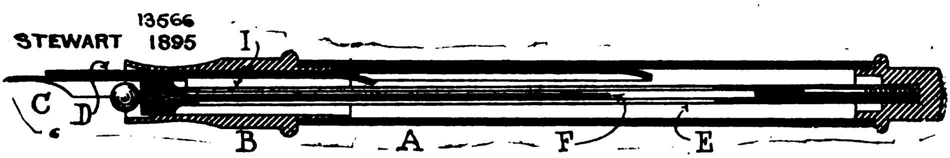


FIG. 61.

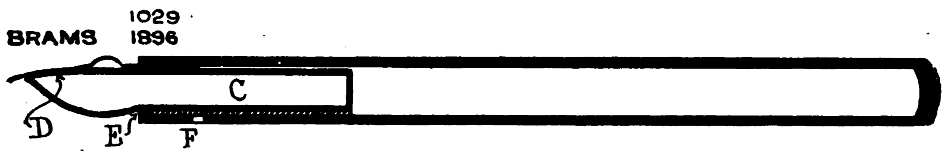

FIG. 62.

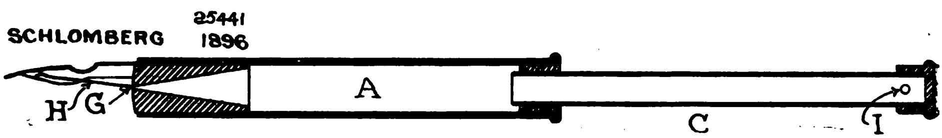

FIG. 63.

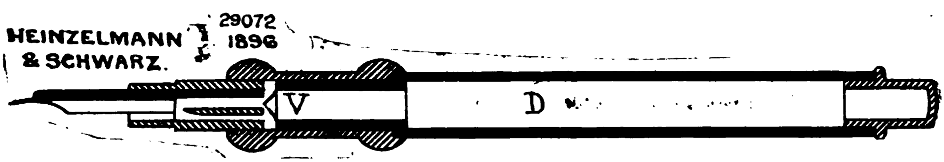

This invention, I. Golwer, 1896 (2189), relates more particularly to the method of controlling the supply of ink to the nib. The ink is contained in the back part of the holder and passes forward through the tube. By depressing the rear end of a lever the valve is raised, and ink flows outwards along the feeder to the nib.

In another pen, C. J. Renz, 1896 (16733), ink is contained in a reservoir, having an air inlet at its upper end. The ink outlet is opened by pushing back the ink conducting piece, thus moving a valve from its seat. Ink then flows in such a position as to conduct the ink to the nib.

The pen shown in Fig. 63 (29072, Heinzelmann and Schwarz, 1896) has a valve, V, of conical form and two or more channels for the ink, which may be partially or completely closed by screwing in the part, D, which is formed at its lower end to fit V.

The specification of this inventor, E. Reisert, 1897 (924), shows a variety of forms of feeding arrangements, from which I have selected as an illustration the one shown in Fig. 64. An intermediate chamber, A, formed

of flexible rubber, is placed between the ink reservoir, I, and the nib, N. It is connected with the reservoir by a tube, E, having a valve opening downwards, and at the lower end it is connected with the nib by a tube, O, having an opening at its side which is normally closed by the spring valve, S, opening outwards. In use the flexible chamber, A, is lightly pressed so that the valve, E, is closed and the valve, S, is opened, thus forcing a supply of ink to the nib. On relieving the pressure the valve, S, automatically closes, and valve, E, opens, admitting a fresh charge of ink to the chamber, A.

Fig. 65 (Bryant and Townsend, 1897, 11516) is a self-filling pen, similar in some respects to others. When sufficient ink has been drawn into the reservoir by the withdrawal of the glass tubular plunger, D, it is allowed to flow into the hollow plunger, which is then pushed downwards into the holder. The ink passages between the reservoir and the nib, C, are not shown, but I would call attention to the annular passage at the bottom of the reservoir being completely closed by the plunger, D, thus making the pen safe to carry in the pocket without fear of leakage, the plunger being firmly screwed down by means of the cap, K, to which it is secured.

Another inventor essays to produce a piston pen (W. C. Sherman, 1897, 19760). The piston is operated by a sliding case connected to the piston-rod which is screwed into the plug at its upper end.

In Fig. 66 (A. Oidtmann, 1897, 20199), the nib, C, is held in place by the elastic ball, F, which entirely closes the ink outlet when the nib is withdrawn. The nib is provided with grooves which conduct the ink to the point.

FIG. 64.

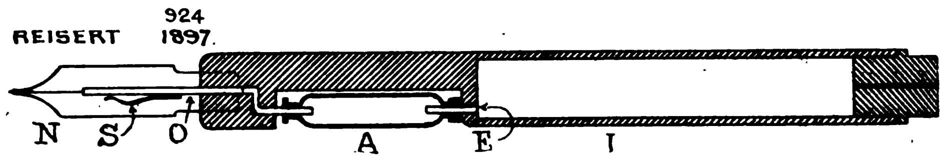

FIG. 65.

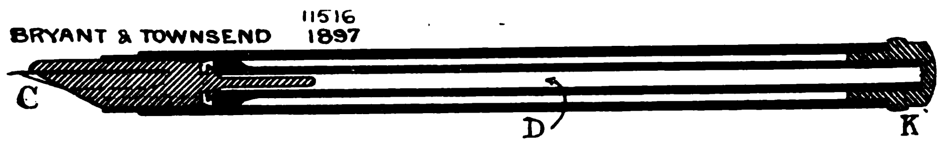

FIG. 66.

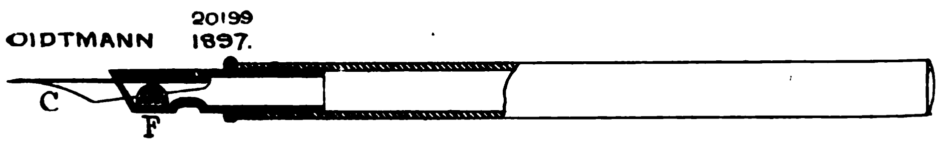

FIG. 67.

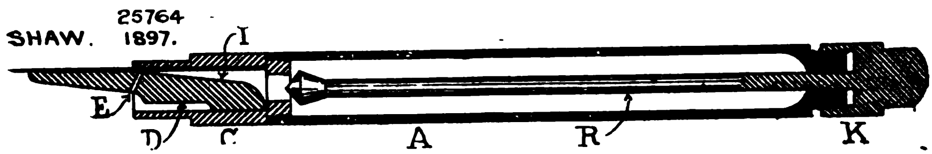


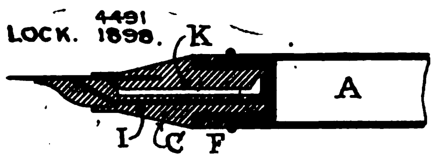
Another pen, Sugden and Wild, 1897 (21948), is one in which the ink is forced to the nib as required. The screwed piston rod carries a pin which slides in a slot. By rotating one part on the plug, the piston is advanced, and forces ink through the feeder to the nib.

Fig. 67 (W. T. Shaw, 1897, 25764) shows a pen in which the reservoir, A, is fitted with a screw plug or point section, C, into which is fitted a second plug, D, having an ink duct, I.

and an air inlet, E, between the points of which the nib is held. The rod, R, may be screwed down by means of the cap, K, so as to completely close the ink passage.

The drawing, Fig. 68 (G. H. Lock, 1898, 4491) is that of the feed point in section. The ink-holding tube, A, is closed by a disc having holes as shown. The plug, C, is provided

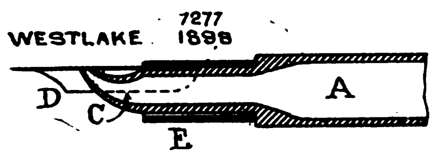
FIG. 68.



with an air channel, I, and and an ink duct, K. This plug can be rotated in the collar, F, so that the holes, by a hit and miss arrangement, become covered, thus either cutting off, or allowing the flow of ink as desired.

The ink reservoir in Fig. 69 (S. N. B. Westlake, 1898, 7277) is closed at one end by a screw plug, and supplies ink to the nib, D,

FIG. 69.



through the curved duct, C. The nib is held beneath the loose sleeve, E. The essence of simplicity certainly, but probably its simplicity is fatal to its satisfactory working.

This pen (Weeks and Morch, 1898, 12244), is designed so that the supply of ink to the nib can be cut off by rotating the head, thus raising the piston, and bringing the valve tight against its seat. Wires are attached to the nib, and extend slightly behind it, and by their vibration are intended to prevent clogging of the channel with ink.

(To be concluded.)

INDUSTRIAL EXHIBITION IN BAVARIA, 1906.

There is to be held in Nuremberg, from May to October, 1906, a general industrial, trade, and art exhibition of the Kingdom of Bavaria. Similar exhibitions, but on a smaller scale, have already been held in that city in the years 1882 and 1896, and they were both attended with great success. The forthcoming exhibition will be held in commemoration of the fact that next year will be the one hundredth anniversary of the raising of Bavaria, hitherto an Electorate, to a Kingdom. It was Napoleon I. who raised Bavaria to the rank of a Kingdom, enlarging it at the same time by important additions of territory, thus showing his gratitude to the Bavarians, his allies at that time, in his war against Austria. According to the American Consul at Nuremberg, the proposed exhibition will be held under the protectorate of Prince Regent Luitpold, the present ruler of Bavaria, and is to give a complete view of all the resources, productions, and industries of the kingdom, which at present has a population of 6,500,000 inhabitants, and an area of 29,343 square miles. The exhibition is to be about forty minutes' walk from the centre of the city, in a newly laid out public park, with a lake adjoining it, and will cover an area of 336 acres, of which half is taken up by the lake itself. The exhibition promises to be a very important one, and according to the Consul is likely to present much of interest to visitors, as there are many articles of manufacture in which Bavaria excels, and which are exported to all parts of the world. Principal among these are toys, lead pencils, and bronze powder. Then plate and window glass and mirrors, lenses, gold and silver trimmings, gloves, glassware, iron and tiled stoves, sewing machines, artistic manufactures in ivory and iron, majolica and faience articles, pianos, guitars and zithers, baskets, coloured gold and silver paper, papier maché goods, altar furniture, flags, banners, embroideries, stained and painted glass windows for churches, &c. The beer breweries of Bavaria have a world-wide reputation, and therefore all apparatus and machinery in the manufacture of the same will be on view. The art department also is expected to be of great interest, Munich being the great art centre of Germany. Very interesting collective exhibits will be made, as for instance, furnished rooms, showing wall, ceiling, and floor decorations, with furniture, curtains, stoves, mirrors, &c. Then the Bavarian Government, the city of Nuremberg, and various other administrations, will make collective exhibits of articles and appliances connected with postal, telegraphic, military, educational, sanitary, and municipal institutions.

MINES AND MINING IN MANCHURIA.

It is known that there are valuable mineral deposits in Manchuria. Coal has been mined for several years in a primitive way, and the operations of the Russians in this direction attracted attention near Mukden. Gold, both in quartz and placer, is found, as is copper, silver, and other minerals; but, as the American Consul at Niuchwang points out, exactly what the

field offers in the way of practical mining possibilities is as yet subject to careful investigation. Many agree, however, that Manchuria is one vast field of mines, and rich farming and grazing lands. Indeed, some of the samples of ore promise great results, but, as a rule, the question which enters into the operation of, and as yet, indeed, the securing of title to, good properties is indefinite and too nebulous at this particular time to prove attractive to capital. With war at an end, and ample and well-defined Government regulations in force, the exploitation of mining enterprises must be open to serious examination. The indications of croppings appear to warrant thorough prospecting of undeveloped properties, and expert opinions, where capital seeks investment in mines that have a right to be called such. Manifestly all matters pertaining to the development of mining properties are practically at a stand-still in Manchuria. In many parts of China, as well as in various other countries, there exists a belief that the mineral deposits of Manchuria are fabulously rich. This belief may, in part, be accounted for by the popular idea that an unknown mineral or gold district possesses great wealth. Previous to the present war, several coal, and a number of gold quartz prospects, held out great inducements, although the Chinese, in a primitive way. have for years been taking gold out of the country. As a rule, however, there has been comparatively little scientific prospecting or investigation. With favourable conditions following the war, the mineral resources of Manchuria will, no doubt, warrant thorough prospecting; without favourable conditions foreign capital probably will be invested with great caution. Applications for mining concessions covering apparently valuable areas in Eastern Manchuria have been put aside for the time being, for one reason or another, but in the main on account of the war. The natives are doing some prospecting, mining, and development work in Manchuria, but foreigners are not thus engaged. The war temporarily at least paralysed mining enterprises. However, it may be said that the samples of ore exhibited at Niuchwang and elsewhere in Manchuria indicate the presence of highly valuable deposits in the various minerals, with several, such as iron, coal and copper, in similar districts covering wide areas. Galena ores recently assayed show, for instance, 1·14 ounces in gold and 1·18 in silver per ton. Various quartz samples assayed showed an average of 0·54 ounces in gold, and as high as 1·25 ounces in silver. Most of the coal has an abundance of slate and ash, although coal of a good qnality has for years been mined in a small way in the Liao Peninsula district. Twenty years ago, for instance, foreign residents in Niuchwang brought their winter's coal supply from the partially-developed mines of Manchuria. Some of these mines have been filled with water, and others have been temporarily abandoned. This coming winter, it is probable that the bulk of the Manchurian coal supply, for domestic purposes, will come from Japan or elsewhere in the Far East.

HOME INDUSTRIES.

The Record Hop Crop.—With the one exception of 1886 the hop crop of the present year is larger than that of any year since the official figures relating to production were first collected in 1885. In 1886 the crop yielded 776,144 cwt., this year it is given at 695,943 cwt., but whereas in 1886 the area under cultivation was 70,127 acres, and the yield per acre 11·07, this year the average was only 48,968 acres, and the yield per acre is 14·10, by far the highest yield on record, the highest hitherto having been 12·76 in 1894, when the total crop was only 661,373 cwts., from an acreage of 51,843. The bad weather this year at ingathering time caused a large proportion of the crop to be more or less off colour, but a third of it is of first-rate quality, and the crop having been grown in a healthy state the off-coloured samples are, from the brewers' point of view, good healthy hops, and full of condition. As the annual consumption of hops for the whole of the United Kingdom ranges from 600,000 to 650,000 cwts. no foreign consignments will be required during the ensuing year. Last year the home yield of hops was only 282,330 cwt., and the value of the hops imported was no less than £1,839,854, the largest sum paid for foreign hops since 1882 when the imports were valued at £2,962,631.

Hop Prices and Profits.—It might be thought that the unprecedented yield of the present year, along with the fair condition of the hops when harvested, would mean very large profits for the hop growers, but this by no means follows, as was shown in the *Journal* of September 1st last. Indeed many of the growers are saying that the last part of their growth has not paid for labour, and a good many are dissatisfied and threaten to root the plant up. Without attaching overmuch importance to grumblings of this kind the following comparative prices, which represented quotations for hops a few days ago—and having been adjusted and revised by the Borough merchants they are not likely to alter materially are suggestive :—

	1904.						1505.					
	£	s.	£	s.	£	s.	£	s.	£	s.	£	s.
East Kent Goldings	9	10	10	10	11	10 ...	2	0	2	16	4	0
Mid Kents	9	0	10	0	10	10 ...	2	0	2	10	3	15
W. of Kents	8	15	9	9	10	0 ...	1	15	2	5	3	10
Sussex	8	15	9	0	9	15 ...	1	15	2	5	3	0
Worcesters.	9	0	10	0	11	0 ...	2	0	2	10	3	10

These figures show an enormous drop from the prices of last year. The lowest price on record was that of the bumper crop of 1886, but even then it only fell to £2 18s. 6d. "Now," to quote from the circular of a well-known hop firm, "good, thick, fat, copper hops are to be got at sixpence per lb. and under." Even a yield like the present one of 14·10 cwts. per acre would only just cover cost of cultivation at £2 16s. per cwt.

Indian and Home Beers.—India has always been one of the chief markets for British beer, but it looks as if our brewers will have to reckon with serious shrinkage in the Indian demand before long. According to a memorandum issued by the Board of Trade through the Indian Office, India is increasing her home production of beer. In 1904 the quantity of beer brewed in India amounted to no less than 6,219,761 gallons, of which 46 per cent. was bought by the army commissariat. There are already 27 breweries of which one at Delhi did not work. All are private property except six, which are owned by five joint stock companies with nominal capital Rs. 24·80·000, of which Rs. 23·89·110 was paid up at the end of 1904-5. Twelve of the breweries are situated at stations in the Himalayas from Murree to Darjeeling, and much of the beer is brewed there. A large quantity is also brewed at Lucknow, Rawalpindi, Poona, Bangalore, Jubbelpore, at and near Ootacumand, and at Quetta and Mandalay. The largest of these breweries is at Murree, the Kassanti and Poona breweries standing next. More than one-third of the whole output is brewed in the Punjab. The exports of beer from the United Kingdom to India in the nine months ended September 30, 1905, show but a very slight falling off as compared with the corresponding period of last year, and over 93 per cent. of the beer imported by water comes from the United Kingdom, but the total imports represent little more than two-thirds of the quantity brewed in India. There would seem to be no good reason why the percentage of Indian brewed beer should not increase.

Brandy v. Whisky.—If the brewers have to keep a watchful eye upon their Indian trade, another home industry finds itself confronted with a change of taste, or fashion, that has checked exports. Until some thirty years ago the favourite spirit in India was brandy, which then gave place to whisky, much to the advantage of a home industry. But recently there have been signs of a return to the old preference, and the figures for 1902-3, 1904-5, show that this change is becoming marked. The proportions imported were (gallons):—

	1902-3.	1903-4.	1904-5.
Whisky	610,327 ..	606,805 ..	589,474
Brandy	322,167 ..	363,359 ..	372,723

Including liqueurs and methylated spirit, the spirits imported into India last year amounted to 1,473,798 gallons, of which 772,350 came from the United Kingdom. The potable spirits imported from other countries are chiefly arrack from Ceylon, rum from the Straits, and gin from Holland.

CORRESPONDENCE.

INCANDESCENT GAS AND ELECTRICITY.

I notice in recent numbers of the *Journal* that under the title of "Home Industries" some remarks have appeared relating to incandescent gas and electricity, and trust you will allow me to suggest that the claims of the advocates of lighting by incandescent gas have not been sufficiently proved to justify the remark contained in the notes that "Electric companies have found a formidable competitor in both house and street lighting in incandescent gas."

Mention is made of the experiments in the street lighting now being carried out by the Corporation of the City of London, and as any reticence regarding the actual facts of the case may give the impression that the merits of the respective methods of illumination are being decided under similar conditions and with equal facilities, I must ask you, in common fairness, to give publicity to the fact that the Corporation of the City of London are apparently giving some preference to a gas company and compressed gas lighting without offering any facilities or making any attempt to ascertain the value of modern electric arc lighting.

The existing arc lighting of the streets of the City is carried out by means of appliances about fifteen years old, and therefore not of the best modern description, and the lamps are also placed in antiquated and extremely ugly lanterns designed by the late engineer to the Corporation, who insisted on their use. These lamps, standards, lanterns, and mains, were supplied free of cost by the Lighting Company, and the charge for maintaining the appliances and lighting was therefore assessed to cover some interest on the capital involved, which was extremely heavy on account of the requirements of the Corporation that the whole of the lighting should be carried out promply and without waiting for the completion of the lighting network of mains. In the case of the gas lighting, however, the Corporation have paid the whole of the capital cost involved; and in spite of this fact the actual cost of lighting by electric arcs works out at about 5d. per candle power per annum as compared with 11d. for gas.

The effective illumination of the two methods can easily be judged by any observer, and it will be found that whereas the electric arc enables the general illumination of the street to be carried out, the use of a short lamppost with an incandescent burner limits the illumination to a confined space round the post, and while useful as indicating the position of the kerb and pavement, such lighting is of no service in obtaining the illumination of the thoroughfare. Such luminous points, even when they are numerous, fail to secure what is really wanted, and that is a sufficient illumination of a street to enable the police to protect the interest of the citizen. If any doubt can be imagined on this point, let an observer visit the Mansion House, where he will see one of the largest compressed gas lamps in operation thrown completely in the shade by the example of modern arc lighting, the cost of running this abnormal gas lamp being something like £65 per annum, without any addition for interest on the capital outlay, and as the light given by this gigantic lamp is only about

900 candles, the cost, without capital charges, works out at about 17d. per cp. per annum.

With these results before us, it is not surprising that many places, including the Deptford Cattle Markets, have thrown out all incandescent gas in favour of the electric arc.

FRANK BAILEY.

Bankside, London, E.C.
31st October, 1905.

GENERAL NOTES.

SOUTHERN NIGERIA.—Summing up the condition of the people of Southern Nigeria (Cd. 2684), the High Commissioner (Mr. Egerton) writes, "The people are typical of the country, in that they are mentally undeveloped, and afford an enormous field for the efforts of the pioneers of civilisation. They are free from direct taxation; they live in comfort, and have few or no cares. On the whole, their lot is a happy one." It would seem so, nor is it certain that they will be grateful for the introduction of a civilisation which, as Mr. Egerton says, "will undoubtedly make the life of the native more strenuous as it becomes more luxurious." Be that as it may, Southern Nigeria is doing well. Mr. Egerton believes the history of the Protectorate to be "unique both for Africa and for other portions of the British Empire. Throughout the whole of the country now under our control settled government has only been established by means of a show of military force, and yet the whole cost of introducing and maintaining law and order—involving the maintenance of a large military establishment—has been defrayed from the local revenues, without incurring any debt. As each year, a larger area has been pacified, a proper system of justice established, free trade between town and town and the coast rendered possible, the increasing revenue has enabled a further area to be similarly dealt with in the succeeding year. In addition to this, large sums have been annually contributed towards the cost of the administration of Northern Nigeria." There seems to be plenty of rain in the Protectorate—the average for the four stations at which records were kept, was 146·87 inches; the highest being at Bonny with 182·84. Road-making is the great want in opening up the country and so breaking down the old barriers of enmity and distrust which have so long existed to the detriment of commerce and the spread of civilising influences.

THE STRAITS SETTLEMENTS.—The figures given in the Governor's Report on the Straits Settlements (Cd. 2684) as to shipping are very striking. The total tonnage entered and cleared in 1904 amounted to 18,267,499 tons. Of this the British flag covered 11,842,744 tons. The foreign tonnage to and from Singapore alone was 12,331,753, Penang taking most of the remainder, 5,180,574. Next in importance to British shipping was German, with 2,859,761 in and out. Under the head of immigration, the figures, as they relate to the Chinese, are given for the last five years and the number of women and children is noticeable. Taking 1904 the figures are as follows: —Men, 179,650; women, 14,395; children, 10,751. The number of "unpaid" passages, *i.e.* of coolies who obtain free passages from China in consideration of entering into contracts for service on arrival in the colonies, has fallen to 16,930. In the last ten years, only two years—1897 and 1898—have shown a lower figure. A few Para rubber estates were started recently on the island, but it is not expected that they will increase to any great extent, as there is not much land suited for this cultivation. In Province Wellesley, and Malacca, however, there is a marked increase in rubber cultivation, and still more so in the Federated Malay States. The area under cultivation in the Peninsula is very large, and the prepared rubber is in great demand by home manufacturers, the best samples having taken the highest price ever paid in 1904, viz., 6s. 1½d. per lb. Indigo cultivation has dwindled to a few fields, and very few of the dyeing houses now remain.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, Nov. 6...Royal Institution, Albemarle-street, W., 5 p.m. General Monthly Meeting.

Engineers, in the Theatre of the United Service Institution, Whitehall, S.W., 7½ p.m. Mr. Sherard Cowper-Coles, "The Metallic Preservation and Ornamentation of Iron and Steel."

Chemical Industry (London Section), Burlington-house, W., 8 p.m. Dr. J. Lewkowitsch, "Evaporation in Vacuo of Solutions containing Solids."

Geographical, University of London, Burlington-gardens, W., 8½ p.m. Rev. Walter Weston, "Travel in the Mountains of Central Japan."

British Architects, 9, Conduit-street, W., 8 p.m. Opening Address by the President, Mr. John Belcher.

London Institution, Finsbury-circus, E.C., 5 p.m. Prof. W. M. Flinders Petrie, "The Egyptians in Sinai."

TUESDAY, Nov. 7....Civil Engineers, 25, Great George-street, S.W., 8 p.m. Sir Alexander Binnie, "Presidential Inaugural Address."

Horticultural, Vincent-square, Westminster, S.W., 3 p.m. Dr. J. A. Voelcker, "Chemistry in Relation to Horticulture."

WEDNESDAY, Nov. 8...Japan Society, 20, Hanover-square, W., 8½ p.m. Mr. Narinori Okoshi, "How the Nikko Temples were Built."

United Service Institution, Whitehall, S.W., 3 p.m. Mr. H. E. Leigh Canney, "The Toleration of Enteric Fever by the Army."

THURSDAY, Nov. 9...London Institution, Finsbury-circus, E.C., 6 p.m. Sir Alexander Mackenzie, "Tchaikowsky."

Electrical Engineers, 25, Great George-street, S.W., 8 p.m. Inaugural Address by the President, Mr. John Gavey.

FRIDAY, Nov. 10...Physical, Royal College of Science, Exhibition-road, South Kensington, 8 p.m. (1) Mr. James Swinburne, "The Question of Temperature and Efficiency of Thermal Radiation." (2) Mr. T. H. Blakesley, "Note on Constant-Deviation Prisms."

Journal of the Society of Arts.

No. 2,764. VOL. LIII.

FRIDAY, NOVEMBER 10, 1905.

All communications for the Society should be addressed to the Secretary, John-street, Adelphi, W.C.

NOTICES.

ARRANGEMENTS FOR THE SESSION.

The First Meeting of the One Hundred-and-Fifty-Second Session will be held on Wednesday Evening, the 15th of November, when an Address will be delivered by SIR OWEN ROBERTS, M.A., D.C.L., F.S.A., Vice-President and Chairman of the Council.

Previous to Christmas there will be Six Ordinary Meetings, one meeting of the Indian Section, and one of the Applied Art Section. The following arrangements have been made:—

ORDINARY MEETINGS.

Wednesday Evenings, at 8 o'clock:—

NOVEMBER 15.—Opening Address of the CHAIRMAN OF COUNCIL.

NOVEMBER 22.—"The Cinematograph and its Applications." By F. MARTIN-DUNCAN. DR. H. E. ARMSTRONG, F.R.S., will preside.

NOVEMBER 29.—"The British Association in South Africa." By SIR WILLIAM H. PREECE, K.C.B., F.R.S.

DECEMBER 6.—"The Manufacture of Sugar from British Grown Beet." By SIGMUND STEIN.

DECEMBER 13.—"The Commerce and Industry of Japan." By W. F. MITCHELL. HIS EXCELLENCY THE JAPANESE AMBASSADOR, will preside.

DECEMBER 20.—"The Aerograph Method of Distributing Colour." By CHARLES L. BURDICK.

Papers for meetings after Christmas:—

"London Traffic." By CAPTAIN G. S. C. SWINTON (L.C.C.).

"The Preparation of Oxygen from Liquid Air." By MONSIEUR RAOUL PICTET.

"Submarine Signalling." By J. B. MILLET.

"The Supply of Electricity." By JAMES N. SHOOLBRED, B.A., M.Inst.C.E.

"The Planting of Waste Lands for Profit." By J. NISBET.

"Industrial Russia." By LUCIEN WOLF.

"The Horseless Carriage, 1885-1905." By CLAUDE JOHNSON.

"The Artistic in Painting and Photography." By J. C. DOLLMAN.

INDIAN SECTION.

Thursday afternoons, at 4.30 o'clock:—

DECEMBER 7.—"The Partition of Bengal." By SIR JAMES A. BOURDILLON, K.C.S.I.

December 7, January 18, February 15, March 15, April 26, May 24.

COLONIAL SECTION.

Tuesday afternoons, at 4.30 o'clock:—

February 6, March 6, April 3, May 1.

APPLIED ART SECTION.

Tuesday Evenings, at 8 o'clock:—

DECEMBER 12.—"Historical Pageants." By LOUIS N. PARKER.

December 12, January 30, February 20, March 20, April 24, May 15.

CANTOR LECTURES.

Monday evenings, at 8 o'clock:—

J. A. FLEMING, D.Sc., F.R.S., "The Measurement of High Frequency Currents and Electric Waves." (In continuation of previous courses on "Electric Oscillations and Electric Waves," and on "Hertzian Wave Telegraphy.") Four Lectures.

November 27, December 4, 11, 18.

SIR WILLIAM WHITE, K.C.B., F.R.S., "The Modern Warship." Five Lectures.

January 29, February 5, 12, 19, 26.

PROF. VIVIAN B. LEWES, "Fire: Fire Risks and Fire Extinction." Four Lectures.

March 12, 19, 26, April 2.

ALFRED MASKELL, "Ivory." Three Lectures.

April 23, 30, May 7.

GEORGE W. EVE, "Heraldry in Relation to the Applied Arts." Three Lectures.

May 14, 21, 28.

Howard Lectures.

A Course of Three Lectures will be given under the Howard Trust, by Professor Silvanus Thompson, D.Sc., F.R.S., on "High Speed Electric Generators, with special reference to driving by Steam-turbines," on the followng Thursday Evenings, at 8 o'clock:—January 18th and 25th, and February 1st.

Juvenile Lectures.

Two lectures suitable for a Juvenile audience will be delivered on Wednesday evenings, January 3rd and 10th, 1906, at 7 o'clock, by Professor Herbert Jackson, on "Flame and Combustion."

PROCEEDINGS OF THE SOCIETY.

CANTOR LECTURES.

RESERVOIR, STYLOGRAPHIC, AND FOUNTAIN PENS.

By James P. Maginnis,
A.M.Inst.C.E., M.Inst.Mech.E.

Lecture III.—Delivered February 6, 1905.

(*Concluded from p.* 1189.)

In Fig. 70 (O. Winkler, 1898, 12805), the hollow ink holding pen handle, A, is by preference made of glass, and is tapered and curved at the forward end to supply the nib, N, which is held in the sliding barrel, B. The rubber air ball, C, is fitted with a sliding valve, V, to control the admission of air, and thus regulate the flow of ink.

The Eagle Pencil Company has designed (1898, 15766), some forms of feed bars, or ink-feeding plugs, as the inventor calls them, for conveying ink from the reservoir to the nib. One of these consists of a tube slotted along the top to receive a tongue, which separates it into two unequal channels.

Fig. 71 (J. Blair, 1898, 17118), shows in part section a reservoir pen in which powdered ink is used. A dry ink cartridge, C, is carried in a porous bag, covered at its forward end by a piece of sponge, S. Soft water is poured into the reservoir to dissolve the ink powder. Otherwise this pen does not call for any remark.

The pen patented by J. H. Burton (1899, 595), was provided with two ink reservoirs and two writing points. One design shows a feed bar having an ink inlet communicating by means of spiral ducts with the ink supply at the upper side, so as to be in contact with the under side of the nib. Another arrangement shows a somewhat similar feed bar provided with a screw thread engaging with the point section, and having an elongated ink duct which tapers towards the inner end, so that by screwing the piece in or out, the ink supply may be regulated.

In the drawing, Fig. 72 (E. Reisert, 1899, 2000), it is seen that the reservoir supplies ink to the nib through the flexible syphon tube, A A. The supply is controlled by pressing on the lever L, at intervals, thus closing and opening the passages at the strictures or valves, V V. Ink enters at the bottom of the reservoir and travels up the shorter limb of the syphon, and is delivered to the nib at the extremity of the longer limb.

Another pen (R. Cofani, 1899, 10869), had a flexible rubber reservoir. The nib is carried in the holder, to which is pivoted the pressure piece. Ink is contained in the reservoir, and is forced through the supply tube by the action of the pressure piece when the nib is brought in contact with the paper.

In F. C. Edgar's pen (1899, 21195), the

Fig 70.

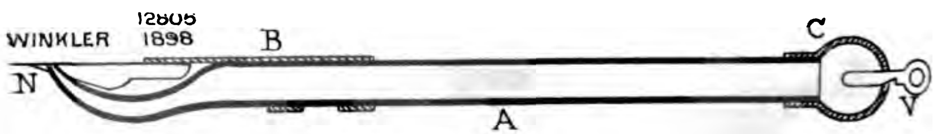


Fig. 71.

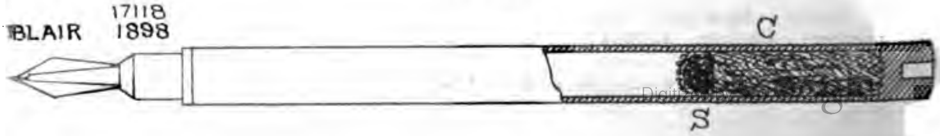
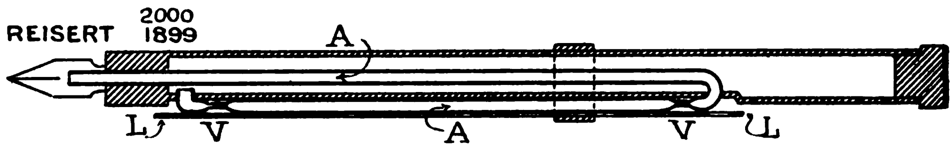


ib is held by the barrel above the elongated pening of the ink duct which is supplied from he reservoir. An outer casing protects the /hole.

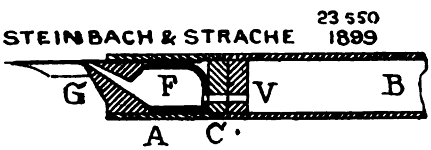
at the back of the casing, A. The ink guide, D, consists of a bent wire terminating in a flat paddle, W. The nib is held in place by the barrel, E.

FIG. 72.



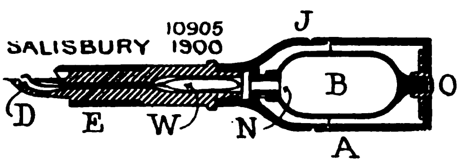
In Fig. 73 (Steinbach and Strache, 1899, 3550) the reservoir, B, and front tubular portion, ι, are screwed on the plug, C. The flexible ubber chamber, F, supplies the nib with ink, hrough the beak, G, and communicates with

FIG. 73.



he reservoir, B, by means of the eccentrically placed channels in the plug, C, and the valve, V. The nib is so secured, that when in use, its nner surface is free to move and depress the surface of the flexible rubber chamber, F.

FIG. 74.



In Fig. 74 (Salisbury, S. M. and E. C., 1900, 10905) the casing, A, is made in two separable parts, connected by a sliding joint, J. The nk reservoir, B, is made of rubber and is attached to the nipple, N, and to the steadying button which loosely fits into an opening, O,

The feed arrangement of another pen (C. J. Holm, 1900, 11049) consists of a plug, provided with a central duct, in which is inserted a short tube leading to a rubber tube, fitted with a glass mouthpiece, which delivers the ink to the nib.

The peculiarity of the pen shown in Fig. 75 (W. F. Cushman, 1900, 11580) is, that when out of use the nib may be withdrawn into the barrel as shown in the drawing. The nib is carried at one end of the spindle, B, sliding through the plug, C, and is connected by the screw-plug, G, with the sleeve, F. When the cap, H, is removed from the front of the pen, the sleeve, F, and the spindle, B, are pushed forward, carrying the nib into position for writing. This appears to be Moore's non-leakable pen.

The ink in F. E. Clarke's pen (1900, 12658) is supplied to the nib through a tube, which may be partly or entirely closed by a tapered wire secured to the screw cap.

In Fig. 76 (H. Grass, 1900, 16558), the nib, N, is shown held in slits in the block, K, and supplied with ink by the sponge or wad contained in the chamber, J. A piston valve, V, is provided at the other end with which the rear end of the ink supply tube, P, may be closed. Extra wads are kept in the upper end of the cap, N.

The nib in Fig. 77 (H. Grass, 1900, 17832), is secured in a slit in the plug, G. Ink passes from the reservoir, B, through the duct, E, and is conveyed to the nib by the spiral spring, L.

FIG. 75.

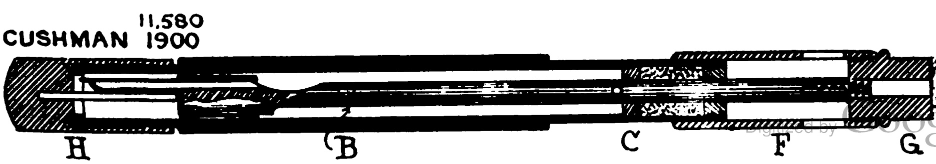


FIG. 76.

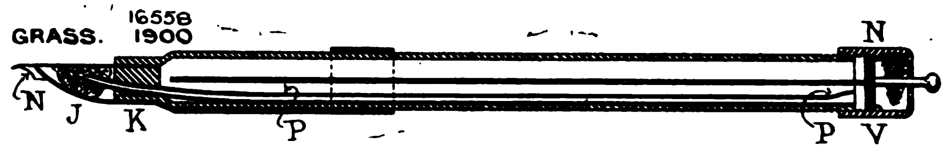

FIG. 77.

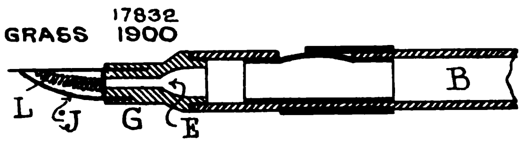

FIG. 78.

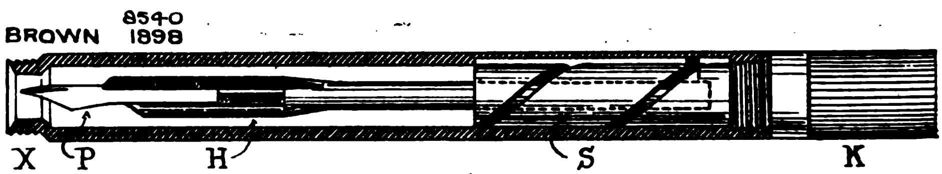


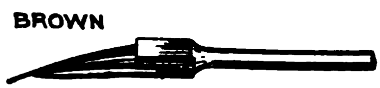
enclosed in the chamber, J. An opening is provided in the outer metallic case, so that the interior flexible rubber reservoir may be compressed slightly by the finger in writing.

In H. W. Dixon's pen (1900, 23567), the ink is sucked into the reservoir by turning the head, until the lower end of the inner tube is unscrewed from the plug. The inner tube may then be slowly withdrawn, and ink thus sucked upwards. When the reservoir is charged sufficiently, further withdrawal of the tube is prevented by wire stops, it is then inverted, and the tube may be moved back into the other extreme position

In Fig. 78 (F. C. Brown, 1898, 8540), the nib, P, is held between the upper and lower tongues of the feed bar, H, which terminates in the form of a rod. A sleeve nut, S, is attached to the cap, K, and may be rotated by it. A pin in the rod, H, fits in the groove of the nut, S, and as the latter is rotated causes the rod, H, to travel in an upward or downward direction, as desired. The nib may thus be drawn within the nozzle, and the cap provided may then be screwed on at X, making a non-leakable joint.

Fig. 79 shows the forward end of the triple feed-bar now used in connection with the pen, known as the Caw pen, and issued by Messrs. Eyre and Spottiswoode.

FIG. 79.



Having now indicated the most important features of many of the fountain pens which have from time to time been invented, I will briefly describe some of those of more modern date or at present in use.

The "Sackett" pen shown in Fig. 80 has already been described in detail. This drawing, however, shows the tongue in plan, and also a cross section of the grooved feed-bar. No further description is perhaps necessary.

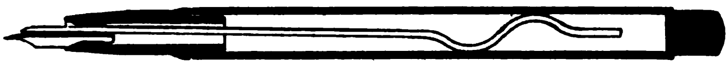
The "Quill" pen, Fig. 81, of Mr. W. S. Hicks, whose name is well known as the maker of pocket pencils, is something like the

FIG. 80.

"Wirt" (described later) as regards its feed-bar. This is, however, about treble the length of that of the Wirt pen, and terminates in a wavy form, as shown, and similar in this respect to the Sackett pen of 1886. The undulations of the feed bar are so designed that they equal the parts are made and fitted together, and the great care exercised in turning out an implement as perfect as possible.

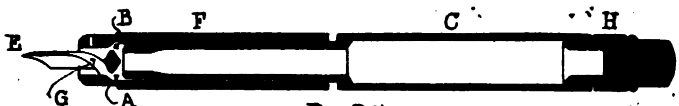
This pen (the "Lacon" pen, Fig. 83) has already been described (see p. 1181), and calls for no further comment.

FIG. 81.



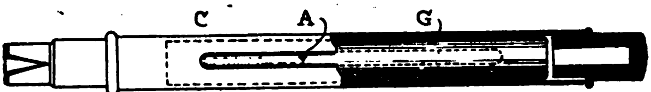
The Quill

FIG. 82.



The Pelican

FIG. 83.



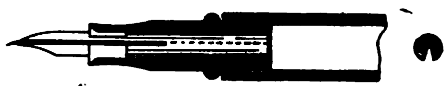
The Lacon.

internal diameter of the barrel or ink reservoir, so that in re-filling the pen with ink it is not necessary to withdraw the feed-bar completely, as the elasticity of the latter, acting against the barrel, holds it in a suitable position to permit of re-filling.

On reference to the drawing, Fig. 82 (De la Rue's "Pelican" Safety Fountain Pen), it will be seen that the holder consists of three parts, viz.:—The pen carrier, F, the body, C, and the plug, H. The body, C, is so constructed that it may be screwed into the pen carrier, F, until it closes the two apertures, A and B. By the reverse process the apertures are opened as shown in the drawing. The lower aperture, A, communicates with the duct, G, whereby the ink is led along the upper surface of the nib to the point, E. The duct, B, at the same time admits an equal volume of air to replace the ink as used in process of writing. The plug, H, is unscrewed for the purpose of re-charging the holder with ink, before doing which the apertures, A and B, must, of course, be closed as already described. By the courtesy and kindness of Mr. Evelyn De la Rue, I have had the privilege of seeing these pens made, and it gave me much pleasure to notice the accuracy with which the various

The feed bar of the "Dragon" pen, shown in Fig. 84) is partly cylindrical with a V-shaped groove extending along its under side. The front end is prolonged in the form

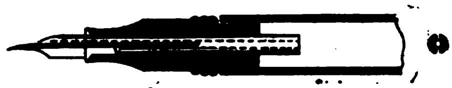
FIG. 84.



The Dragon

of a tongue which rests on the upper surface of the nib. The pen from which this drawing was made was submitted to me by the American Pencil Company. It has a tapering cap which is perhaps an advantage, as it tends to keep a better balance when writing.

FIG. 85.



The Camel

The feed bar of the "Camel" pen, of Messrs Ormiston and Glass, in Fig. 85, consists of a single rod fitting into a point section. It has

grooves and passages for ink and air as shown in the drawing. The front end terminates in a single top feed tongue, and a slit extending backwards about half way for the reception of the nib.

Fig. 86 (the "Fleet" pen) shows an exceedingly low-priced fountain pen, the specimen in

FIG. 86.

The Fenchurch. The Fleet.

my collection costing the modest sum of 6½d. It consists of a barrel or ink reservoir, B, and a plug, P, which almost fills the neck of the barrel. This plug is circular in section, cut away diagonally at the front end, to a point. A saw-cut groove extends longitudinally along its upper side, nearly to the point, whilst underneath is a cut or gash, which almost divides the plug into two parts. This latter acts mechanically as a spring, so that when the nib and plug are together placed in the barrel, both are held firmly in position. It is intended that almost any suitable form of metal or steel nib may be used, and not necessarily a gold one.

The "Lincoln" pen shown in Fig. 87 has nothing very special to speak of. It has a simple form of single undertype feed, and the

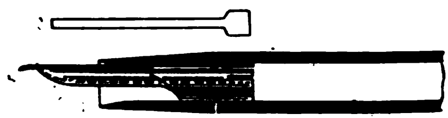
FIG. 87.

The Lincoln

pen takes its name from that of one of the most popular of the United States Presidents. I am informed by Messrs. Deverell, Sharpe and Gibson that Messrs. Perry and Co. claim the name, "Lincoln," as applied to pens of all descriptions, so that the "Lincoln" fountain pen is now known as the "Devarson," a name built up of syllables from the names of the members of the firm. Since writing the foregoing, I have tested the "Devarson" pen, and I can vouch for its excellence. The feed is simple, and effective.

Fig. 88 shows the business end of the "Stafford" pen. Like Fig. 87, and many other pens of very high excellence, it is produced in the United States. Its feed bar is a combination of that of the Waterman pen of 1884, in that it has parallel saw-cut ducts extending along its upper half, and it also resembles the feed bar of Prince's pen of 1855, in that it has a thin vulcanite tongue, a plan of which is shown on the drawing, which lies along the ink duct and vibrates with the action of the nib. The feed is very satisfactory, and I like the pen on account of its capacity for ink. Although I have fitted it with a "Swan" nib, I have found it very reliable.

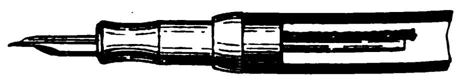
FIG. 88.



The Stafford

Fig. 89 shows the point section of the "Swallow" pen, and just enough of the feed arrangement is visible to show that it bears a very striking resemblance to that of the Swan

FIG. 89.



The Swallow.

pen of 1895. Imitation is said to be the most sincere form of flattery, and probably the maker of the Swallow pen knows a good thing when he sees it.

In Fig. 90 is shown the point of the "Parker" pen, known as the "lucky curve" pen. A saw cut commences at the rear end of the feed bar, almost dividing it in two parts, and then

FIG. 90.

The Parker

traverses the upper surface, reaching nearly to the point, where it disappears. Air is admitted through a small hole, entering at the under side, as indicated by the arrow, and passes upwards to the saw cut.

The "Swan" pen (Fig. 91) is perhaps a household word. There are those who think, or perhaps they do not think, that the name "Remington" covers all typewriting machines that ever were invented. Some firmly think that all hand cameras are Kodaks, and there are also many who no doubt think that "Swan" is a sort of generic name for fountain pens. Be that as it may, Messrs. Mabie, Todd and Bard have not been wanting in energy and painstaking ability to make the fountain pen popular. Their pens are known, and deservedly so, throughout the civilised world. As a matter of fact I wrote these words with one of their gold nibs purchased thousands of miles away, and used for many years in the Friendly Islands. It now glides smoothly and silently along, although it is adapted to a different holder and feed arrangement to that for which it was originally intended. The feed arrangement of the "Swan" consists of two parts. The feed bar is of the double type, that is to say, the bar is divided for about one half its entire length into two tongues, between which the gold nib is placed so that there is a tongue on the top of the nib which reaches to within a short distance of its point, and a second tongue lies snugly on the underside of the nib, being about $\frac{1}{8}$th or $\frac{1}{10}$ths of of an inch shorter than the upper one. This feed bar being originally tubular is grooved longitudinally along its inner surface forming ducts whereby the ink is led to the nib. Besides the feed bar proper, there is a twisted silver wire, the polished surface of which repels the ink, and in doing so provides a means of conducting air to the ink chamber, thereby completing the circulation. Without unduly giving prominence to the "Swan" pens, I would say that I have carried one of them for some time, and I have always found it reliable. It is always ready to write as soon as it touches paper, and it has never yet emptied its contents where not required. Mr. Watts, the London manager of this firm, has rendered me much service in connection with my lectures, in showing me many pens now obsolete, whilst on the other hand I have had pleasure in showing to him others, of the existence of which he had not previously known.

In Waterman's "Ideal" Fountain Pen (Fig. 92) the great charm lies in its simplicity. In every fountain pen the feed is the all-important detail that makes or mars its success. The feed of the Ideal is the essence of simplicity. It is strong, and unlikely to get out of order, and it ensures a copious supply of ink at the business end of the nib, without fear of delivering it too quickly. The drawing shows one of these pens in section. It will be noted that the feed bar, B, contains a grooved duct or passage, extending almost to its entire length. This duct is about one-sixteenth of an inch wide, and along the bottom of the duct are parallel saw cuts by which the capillary action is secured. Cross sections of the feed bar were shown earlier. A later improvement has been effected. On either side of the duct, pockets or recesses are formed, which were not shown on the previous drawings. These pockets are designed to collect any surplus ink, and hold it in readiness to meet the requirements of the nib. This form of feed allows practically the whole of the barrel to be at disposal as an ink reservoir, as there are no internal projections. It is stated by the manufacturers that their pens will hold sufficient ink to write from 16,000 to 30,000 words. I have given two of these pens a severe trial, and the only fault I have to find with them is that they will not write without ink. Mr. Symonds, of Messrs. Mordan and Co., as well as Mr. Sloan, of Messrs. Hardmuth and Co., have been good enough to give me many facilities for testing these pens.

FIG. 91.

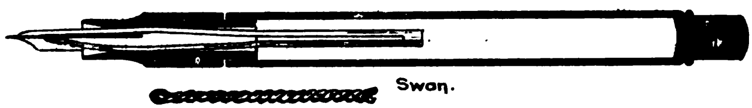


FIG. 92.

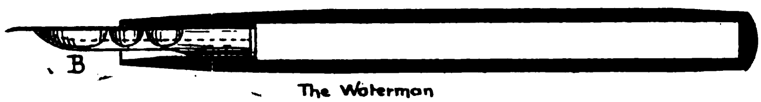
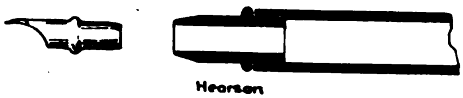


In Fig. 93 is a drawing of the "Hearson" pen, consisting of three parts, viz., the reservoir, the point section, and the nib of barrel

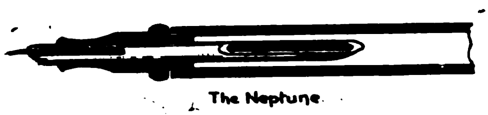
FIG. 93.



type. It will be remembered that this has already been described in detail, as having a steel barrel nib enveloped in an india-rubber casing (see p. 1174).

Fig. 94 shows the feed bar of the "Neptune" Fountain Pen. It will be seen to consist of a tube having a longitudinal slice cut from the rear end, whilst the other or front end is formed into two blades or fingers, one of which lies above the nib, and the other below it, in close contact. Sometimes there is only one finger,

FIG. 94.



or, in other words, a single feed. I need hardly call attention to the fact that there are three different kinds of feed used in fountain pens, viz.:—Single feed, top; single feed, bottom; double feed, top and bottom; one or other of which is adopted.

Fig. 95 is the "Wirt" pen (P. E. Wirt, 1885, 1496). This is a pen of the single feed type. The feed bar, too, is on the top of the nib. The feed bar consists of a single blade of vulcanite, about 2½ inches long, reaching nearly to the point of the nib, and extending backwards into the ink reservoir, the rear part being formed somewhat like a paddle or oar. Air finds its way under the nib, and bubbles upwards through the body of ink, whilst the ink by capillary force is fed along the bar. In general appearance the Wirt pen is very like other fountain pens. I had the good fortune to become possessed of one of these pens, which I used regularly for nine or ten years, and it is still as good as new. The drawing now shown is taken from the pen referred to, and the manufacturers have recently afforded me an opportunity to test a more modern pen, which I find equally efficient.

Moore's "Non-leakable" pen (Fig. 96) is another of those pens designed to prevent leakage when carried in the pocket, and it fully justifies what is thus claimed for it. The pen, or nib, can be drawn within the barrel by means of the slide or thimble, S, attached to the rear end of the elongated feed, F, which passes through the end of the barrel, and is screwed into the plug, P. A stop pin, A, prevents too much movement. The cap is provided with a screw thread, by which it can be securely screwed on the open end of the barrel, thus ensuring a sealed joint. A projecting rod, C, in the cap prevents any injury to the point of the nib when the cap is screwed down, as it abuts against the plug, P, and prevents any movement of the pen. I have given four of these pens a severe trial, and cannot speak too highly of them. They appear to be absolutely non-leakable when closed, no matter in what position they may be carried, and under all conditions they are perfect of their kind.

FIG. 95.

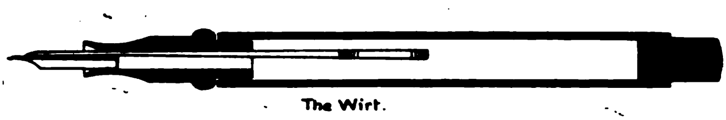


FIG. 96.

The "Horton" pen, shown in section in Fig. 97, is very similar to the following pen. It will be noted, however, that the sleeve nut

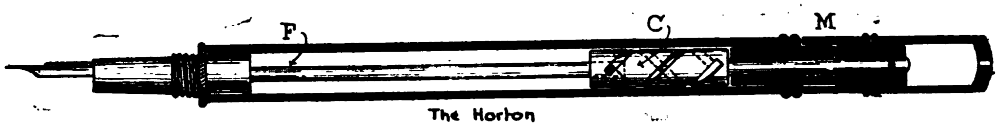
has a double groove or thread, and also that there is a movable point section, but the movements are otherwise identical.

The distinctive feature of "Caw's Safety" Fountain Pen (Fig. 98) is the method whereby the pen-point is made to recede into the ink holder. The illustration shows clearly how this is effected. It will be seen that the feed bar, F, into which is fixed the nib, is elongated, and its rear end enters a cylinder having a spiral groove cut in it. A pin attached to the feed bar passes through the spiral groove, and is free to slide up or down in a straight groove cut in the barrel of the pen. The cylinder, C, is attached to the milled portion, M, of the pen, and on turning M, the cylinder, C, revolves with it, causing the feed bar, F, to travel, and the nib is thus propelled or withdrawn into the reservoir of ink; if the latter is desired, then the cap is screwed on at K, preventing the outflow of ink in whatever position the pen may be carried. It will be evident that when the nib is propelled, the feed bar, enlarged at that point, closes up the restricted aperture of the barrel, so that no ink can escape other than is required to supply the nib. I have tested one of these pens, which Messrs. Eyre and Spottiswoode kindly sent for my inspection a few days ago, and I find that it leaves nothing to be desired.

The "Swift" pen (Fig. 99) belongs to that class which makes special provision against risk of leakage, when out of use or when lying in a horizontal position. This end is accomplished by means of the valve, V, operated from the upper end, E, of the pen, which when screwed down, closes the ink-passage. The feed is of a very simple description, as may be seen. The ink passes along the tapering channel to the under side of the pen, I, air being admitted at the opening, A. The nib being fixed in the slit, N, provided for it. It appears to be identical with W. T. Shaw's patent of 1897, already described and illustrated (see p. 1188).

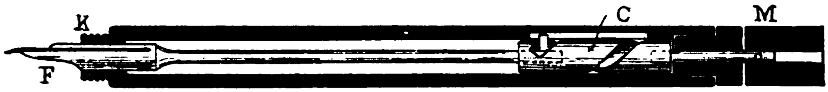
An early form of pen (Fig. 100) of the self-filling type is the "Automatic." The specimen I am about to describe has been in my possesion since about 1878. It is constructed entirely of metal with the exception of the ink container, I, which is a flexible rubber tube closed at one end, and attached to the feed point, F, at the other end. In the casing, B, is an opening, A, placed in such a position that the thumb may

Fig. 97.



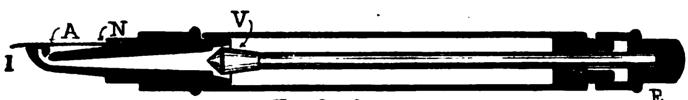
The Horton

Fig. 98.



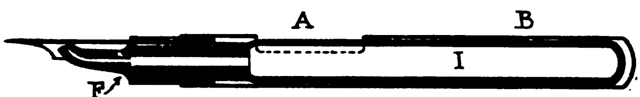
Caw's Safety

Fig. 99.



The Swift

Fig. 100.



The Automatic

readily be placed upon it so as to create a pressure on the ink container, I, and thus force a supply of ink to the nib as required. To fill the pen, the casing, B, is removed, the container is compressed to expel all the air, and placing the point in an ink bottle, the container is allowed to expand when it becomes charged with ink. A cap is provided for the protection of the nib. This pen differs in one respect from that of Michell, in that the ink is delivered underneath the nib, whereas it will be remembered, perhaps, that in Michell's patent, the ink was delivered on the back of the nib (see p. 1177).

The "Conklin" pen, shown in Fig. 101, is an improved form of the "Automatic" just de-

FIG. 101.

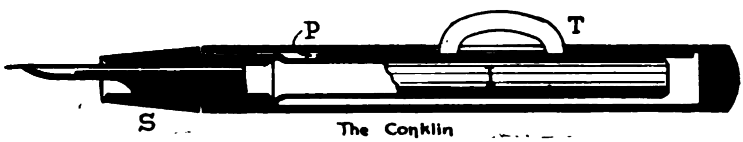


FIG. 102.

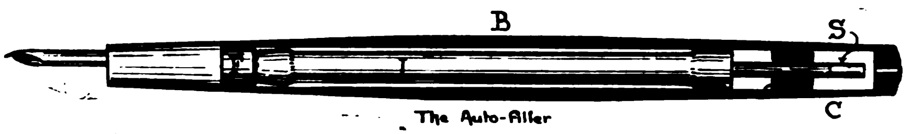

FIG. 103.

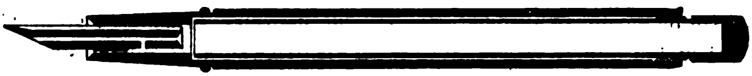
scribed. Its method of refilling is precisely the same, but a pressure bar, P, is provided, which extends practically the entire length of the flexible ink container, I. When the thumb-piece, T, is pressed down the container, I, is flattened, and thus it is emptied of air. The casing of the pen is of vulcanite, and the point section, S, is fitted into it without any screw thread, as an ink tight joint is unnecessary. The ink-container may be readily and cheaply renewed when necessary, and for those who like a self-filling pen this one ought to find favour. The method of filling will be shown presently.

The "Autofiller," shown in Fig. 102, is, as its name implies, a self-filling pen, whose ink container, like that of the "Automatic," consists of a soft rubber tube, I, the rear end of which is closed by a plug, prolonged in spindle form, which spindle, S, projects through the end of the barrel, B, when the small cap, C, is removed. The other end of the container, I, clasps the "feed," F. The spindle, S, may be revolved by the finger and thumb, and the act of doing so causes the rubber container to twist, as the lower end is held fast, thus driving the air out of the container. Placing the point in the ink, and allowing the container to straighten out slowly from its twisted form, the ink quickly rises and fills the container. The disadvantage of these pens lies in the flexible container, which quickly perishes, but a new tube may be had at a very trifling cost, and may be readily substituted for the old one, when the pen will have a new lease of life. The "Autofiller" is very similar to the Conklin pen, the chief difference being the method of manipulating the flexible ink reservoir, by twisting instead of by pressure.

The "Post" pen, illustrated in Fig. 103, and already described, is a pen constructed on the syringe principle. A piston, P, fits the barrel, B, and is operated by the piston rod, R. The idea being to fill the pen by means of the piston arrangement, just as a syringe may be filled. There is nothing special about the feed arrangement, but an ingenious method is adopted of elongating the piston rod. This rod is hollow, and an extension rod, E, is provided, which, when not required for use, slides into the hollow rod, lying snugly out of the way. It may be withdrawn a short distance, and then a couple of turns screws it into the rod, R, thus making it a more convenient length to use. Before replacing the cap which covers

ıe piston rod, when the pen is in use, the rod, , is unscrewed and slid back into R, thus ıaintaining the length of the pen as normal. . small cap is provided to protect the nib 'hen out of use. The "Post" pen is very well

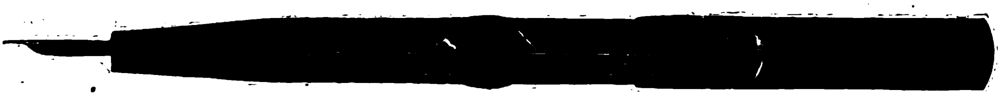
FIG. 104



The Eagle Pencil Co.

FIG. 105.

FIG. 106.



nade, it is an excellent form of self-filling pen, ɔut the ink-holding capacity is small. It may ɔe of interest to state that the Salvation Army s responsible for its introduction into this ɔountry.

Fig. 104 shows a section of the fountain pen of the Eagle Pencil Company, a firm well known for its ingenious automatic pencil holders. It will be seen that the barrel and point section are in one piece, and that a second barrel, screwed into the first at its upper end, reaches downwards to the feed bar. This inner barrel may be entirely removed and filled with ink in the manner generally adopted, and then returned to the position shown in its outer case, thus keeping joints free from ink. The feed bar has a hole drilled right through its centre line from end to end, and a branch leading downwards for the admission of air, whilst ink passes along the groove on its upper side to the underside of the nib, which is not shown in the drawing.

In Figs. 105 and 106 appear two excellent sectional views of the "Conklin" pen. The upper one shows clearly the flexible rubber reservoir fully distended, and ready for use. A metal band passes nearly round the casing and through the opening formed in the thumb-piece of the presser bar. In the position shown in the upper view, the presser bar is inoperative, but when the gap in the metal band is brought into the position shown in the lower view, the reservoir may be compressed for filling.

Fig. 107 (H. Siegert, 1892, 4739) shows a fountain pen in which the penholder, C, is connected by a flexible rubber tube, B, to an ink bottle, E, the tube passing through a cork or stopper fixed in the bottle, and reaching

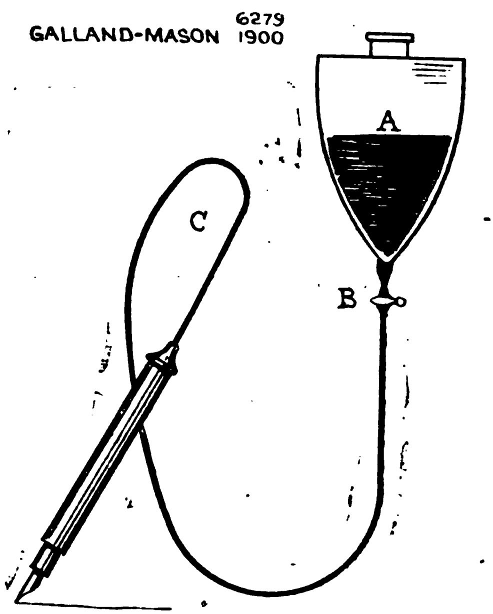
FIG. 107.

down to the bottom. A second tube with a rubber ball, D, also passes through the stopper, but does not reach so far downwards as to

touch the ink. By squeezing the ball, D, the pressure of air is increased and ink is forced into the penholder, C. The inventor suggests that several pens may be connected to the same ink bottle, each having its flexible connection.

In this drawing, Fig. 108 (R. Galland-Mason, 1900, 6279), the ink vessel, A, is connected to a fountain pen by means of a rubber capillary tube, C. The ink flow is regulated by a

FIG. 108.



spring clip, B, which may be placed in any convenient position. The idea is very similar to the previous one, but differs in this respect. In the former case the ink arrives at its destination by a syphonic action, stimulated by the action of the rubber ball, whereas in the latter the ink flows by gravity.

Fig. 109 represents a neat little pen sold by Messrs. Eyre and Spottiswoode at the modest price of threepence. The ink-reservoir is made of brass, as many Birmingham productions are, and it is intended to be used in combination with any ordinary steel nib which may fit. The nib is held in position by the plug of vulcanite shown underneath it, the cut in which gives it a springlike grip. In this respect it is similar to the "Fleet" or "Fenchurch" pen (p. 1198). Ink is fed to the nib by the saw-cut extending along the upper length of the plug, and which, when in position lies immediately under the nib. The stricture shown in the barrel prevents the plug from being thrust too far inwards.

Messrs. Myers and Son have no intention of being outdone in the matter of price, for in Fig. 110 we have a fountain pen retailed at the very moderate price of one penny. He would indeed be a careful man who expected a fountain pen for less. Like the pen just described, the ink reservoir is of brass. The nib, however, is specially made for the pen, and has a grooved air channel extending along from the butt to about half the length of the nib. The nib is held in a metal penholder continued underneath the point of the nib as shown in the drawing, and capable of holding a considerable quantity of ink. A slip of wood is inserted in the rear of the penholder to form an ink feeder.

Messrs. Myers have sent me some of these pens, and I am pleased to find that they are really workable. Truly, no one need be without a fountain pen.

I feel that I have nothing to teach those who have been, and are still, designing fountain pens, but perhaps the general public will allow me to tell them how I keep my fountain pens clean. It is, as I dare say many know to their cost, a great mistake

FIG. 109.

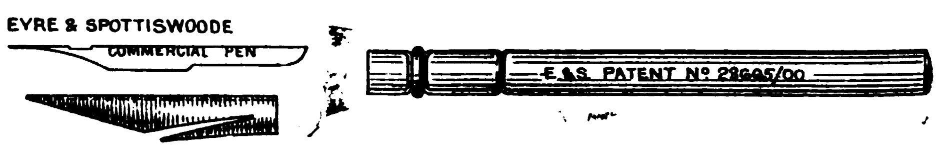


FIG. 110.

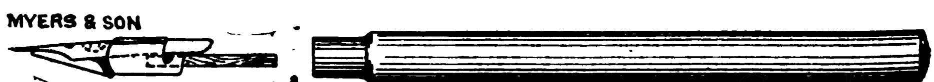


for those inexperienced in such matters, to attempt to take all the parts of a fountain pen out of their proper place, owing to the difficulty experienced in putting the various parts back in their correct relative positions. It is also a difficult matter to thoroughly cleanse the minute passages, and free them from foreign matter which will get there, and which becomes hardened and obstructs the flow of ink and air.

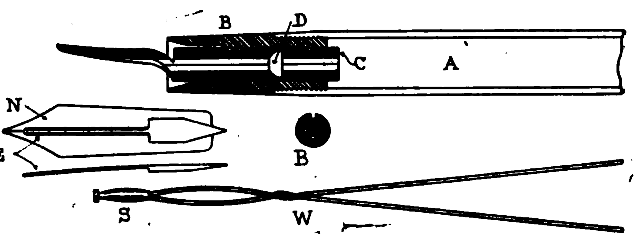
The simple device I have shown in Fig. 111 is most effective in its action. It consists of one of the little pipette tubes supplied with fountain pens, fitted into a cork slightly tapered, as you can see. This I place in the water supply tap, with the result that a fine jet of water is produced, issuing from the point at a considerable pressure, so strong that if the point section of the pen be unscrewed and the jet allowed to play into the passages, all impurities will quickly disappear, and the pen be thoroughly cleansed. This is not patented, but it works just as well as if it were, and I advise fountain pen users to try it.

I now want to show you the internal arrangements of the latest "Swan" pen. Fig. 112 shows the ink reservoir, A, into which is screwed the point section, B. A vulcanite plug, C, fits loosely into the point section, and extends in the form of a tapering finger, underneath the nib, reaching nearly to its point. This plug is pierced along its axis by a rectangular hole, and an enlarged chamber is formed at D. A narrow tongue of metal, E, shaped somewhat like a nib at its rear end, lies along the back of the writing nib, N. The double wire, W, has at one end a tiny tapering plug or stopper, S. When the parts are fitted together, this wire passes through the rectangular hole in the plug, C, and the little stopper, S, occupies a position in the forward end as shown in cross section at B, a round stick in a square hole, thus leaving the four corners open for the admission of air. To fill the reservoir, it is only necessary to slightly withdraw the stopper, S, and the air readily finds its way out, through the square hole referred to, whilst the ink presses inwards.

Mr. Watts kindly sent me two of these pens for experimental purposes, one of these being of ordinary proportions, and the other of noble dimensions. I am much pleased with them, especially the latter, and to give some idea of its capacity for ink as compared with other well-known pens, I have here in Fig. 113 shown it alongside, the "Waterman" pen, a pen of which I cannot speak too highly, whilst below it will be seen the penny pen of Messrs. Myers. Shall I call them "Dignity and Impudence," or "The Sublime and the Ridiculous"?

FIG. 111.

FIG. 112.



One word as to the cap. There appears to be a tendency to provide a cap which perhaps, to many, is clumsy. Its appearance is evident in the drawings of the "Waterman" and the "Swan" pens. To those who want to know why it is being adopted, I would point out that it is designed as a safeguard against any possible leakage at the joint between the ink reservoir and the point section, which it completely covers, and it fulfills its mission admirably. It might, however, in my humble opinion be improved in design.

Finally, I would repeat that it has not been my intention to make invidious distinctions

with regard to any particular make of pen; on the contrary I have endeavoured to describe one and all impartially. Where I have had opportunities of testing any of the pens I have spoken of them as I found them, and when I have had any praise to bestow it has been given because I considered such was due. It must not be understood, however, that many other pens may not have equally good features.

It may possibly have been a shock to some to find that the modern fouutain pen is the outcome of ideas so old, but after all has been said and done, the most ingenious, or the simplest, or the most scientifically designed fountain pen is bound to be a failure unless it be properly made and properly adjusted. Be the invention old, or be it new, it cannot help but fail in its object, if the skilful hand and intelligent mind of the artisan are not brought to bear on its production.

Perhaps a fitting termination to this lecture would be a description of a fountain pen which my friend, Mr. Bennett H. Brough, has brought to light in a volume published in 1723, being an English translation of Monsieur M. Bion's work on Mathematical Instruments, written and published in French some years previously, in which the instrument was called "Plume sans fin," a pen without end. It is, however, in the English translation called a fountain pen. Here is a copy of the drawing (Fig. 114) of the fountain pen which appears in the book, and it will be noticed that the nib employed looks very like a quill. The descriptive matter is very quaint, and I reproduce it here.

Extract from Edmund Stone's translation, 1723, of M. Bion's work on Mathematical Instruments :—

"Of the Fountain Pen.—This instrument is composed of different pieces of brass, silver, &c.; and when the pieces, F, G, H, are put together, they are about five inches long, and its diameter is about three lines. The middle piece, F, carries the pen, which ought to be well slit, and cut, and screwed into the inside of a little pipe, which is soldered to another pipe of the same bigness, as the lid, G; in which lid is soldered a male screw, for screwing on the cover: as likewise for stopping a little hole at the place I, and so hindering the ink from running through it. At the other end of the piece, F, there is a little pipe, on the outside of which the top-cover, H, may be screwed on. In this top-cover there goes a porte-craion, that is to screw into the last-mentioned little pipe, and so stop the end of the pipe at which the ink is poured in, by means of a funnel. When the aforementioned pen is to be used, the cover, G, must be taken off, and the pen a little shaken, in order to make the ink run freely. Note.—If the porte-craion does not stop the mouth of the piece, F, the air, by its pressure, will cause the ink to run out at once. Note, also, that some of these pens have seals soldered at their ends."

FIG. 113.

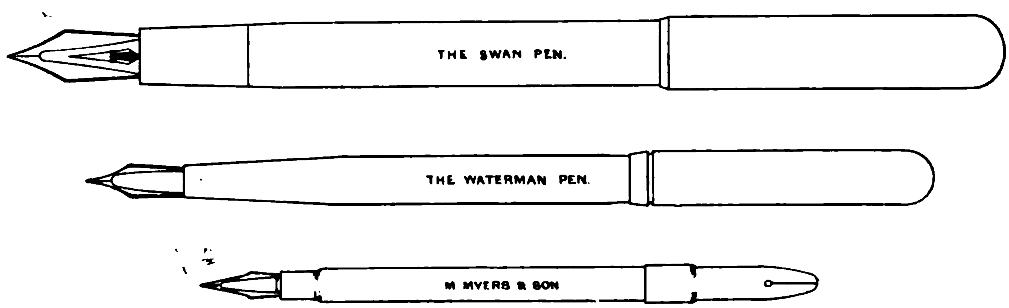


FIG. 114.

HOME INDUSTRIES.

Thames Shipbuilding.—Although the announcement that Messrs. Yarrow and Co. intend to leave the Thames was not unexpected—they have been credited with the intention for the past two years—it is not surprising that it has served to direct attention to the position of industrial London as compared with great provincial centres. Messrs. Yarrow's decision to remove at what must be great inconvenience and cost to themselves is not due to any one cause but rather to many. The popular explanation is the rise in rates, but this is only one, and not the main, consideration that has led to the decision. At 12s. in the £ Poplar is more highly rated than any other district in London, but a saving of £1,000 a year, or something of the kind, would not of itself have induced removal. High rates are only one of the drawbacks with which the shipbuilder has to reckon whose works are on the Thames. The rating of machinery, which is so serious a matter in London, is escaped, or is much lighter, elsewhere; wages are higher in London than in the North, steel plates cost more, coal costs more, material generally costs more on account of the distance which it has to be brought. In leaving London Messrs. Yarrow do not make a new departure. They follow where others have led. Allen's have gone to Bedford; Willans and Robinson to Rugby; Simpson to Newark; Siemens are doing much of their work at Stafford, and Thornycrofts at Southampton. Messrs. Yarrow have held on longer than most, but they too have to bow to the economic causes that have prevailed with other firms.

The Foreign Transhipment Trade.—It is with shipbuilding on the Thames as with its foreign transport trade, consisting in the import of goods destined for immediate or eventual transport to the Continent of Europe, or to other parts of the world. Both the inland and the export trade of London have lost ground relatively to other ports, and to a large extent this has been unavoidable. Formerly, as Mr. D. Owen, a high authority on the subject, pointed out in his evidence before the Commission on the Administration of the Port of London, London was a distributing and collecting port, as being the world's trade focus, the world's market. The cargoes came to the biggest market. The Low Countries and the Continent bought in London, and sent goods to London for shipment. London was the "goods exchange" for Europe to a large extent. But the position is greatly changed. The abolition of the Scheldt dues threw open Antwerp, which at once began to compete with London. The opening of the Suez Canal was soon followed by ships being ordered with full cargoes to Antwerp, Hamburg, Rotterdam, Havre, and other places. This competition, powerful as it is, is still only in its infancy. Continental ports are spending lavishly on improvements, and it seems inevitable that the business of London as a port of distribution will decline. And so with shipbuilding. Time was when the shipyards in the Isle of Dogs alone employed from ten to twelve thousand men, but the industry began to move away when rates were only half their present figure. The shipyards are gone, but notwithstanding the rates other industries have taken their place. There is a big jam factory on the site of the yard which built the Great Eastern, and other yards are now occupied by chemical works, an American oil company, and provision works.

Provincial Shipbuilding.—The principal centres of shipbuilding in England have been the Thames, the Tees, the Tyne, and Sunderland on the east coast, and Liverpool, Barrow, and Whitehaven on the west. How seriously London has suffered as compared with other ports will be seen from the following figures which give the number and net tonnage of sailing and other ships built for home requirements in London and elsewhere in recent years:—

	1900.		1904.	
	No.	Net tonnage.	No.	Net tonnage.
London	222	15,424	59	4,040
Newcastle	42	85,128	62	108,047
West Hartlepool ..	22	48,858	19	37,019
Sunderland	54	122,580	63	133,267

These figures show that whilst even in 1900 London had ceased to be a leading shipbuilding centre for home demands, four years later her position was much worse. It is the same if the figures are taken of iron, steel, and wooden sailing and steam vessels built during the year 1904 at ports in the United Kingdom for foreigners:—

	Sailing.		Steam.		Total.	
	No.	Tons net.	No.	Tons net.	No.	Tons net.
London ..	7	347	22	1,153	29	1,500
Newcastle .	—	—	20	32,721	20	32,721
Sunderland	—	—	18	29,042	18	29,042
West Hartlepool ..	—	—	6	12,661	6	12,661
Glasgow ..	28	3,914	31	4,155	59	7,610
Belfast....	—	—	1	669	1	669

Of war vessels Sunderland, West Hartlepool, Glasgow, and Belfast built more, but London built seven small boats of a tonnage of 451 tons, and Newcastle a single vessel of 1,596 tons net. It looks as if before many years have passed London will have ceased to build ships for the foreign as well as the home market.

The Match Trade.—Another company employing a large number of hands in the East End is that of Bryant and May, Limited, the well-known match manufacturers. Located in the district ever since the early days of the match industry, the now well known

"safety matches," invented by Lundström of Sweden in 1855, were first manufactured in the United Kingdom by Bryant and May, who can point to a very prosperous past, but like Messrs. Yarrow they have been considering the advisability of moving their works. "We are," said the managing director last week, "owing to the higher rates, seriously considering the question of moving." The competition in the match trade is very keen, Sweden being the most formidable rival of the English manufacturers, but other countries send us very large supplies as will be seen from the following figures:—

	Gross of Boxes.		Value, 1904.
	1900.	1904.	
			£
Sweden ..	5,293,792	5,620,546	306,365
Belgium ..	1,742,238	2,132,344	97,199
Holland ..	342,475	433,304	18,557
Norway ..	332,210	712,384	35,231

It will be noted that although the imports from abroad are enormous, amounting in 1904 from the four countries named to no less than 8,898,578 gross of boxes, with the exception of Norway, which has more than doubled its export, they do not show any very rapid increase in the four years although in each case there is increase. There can be no doubt that, more especially in Norway and Sweden, the conditions of manufacture are very favourable as compared with England. For example, the wages of the unskilled workman in Sweden average 8s. 2d. per week. It is not surprising that with the foreign article admitted free, and prices here making it possible to buy matches that are not the cheapest for 2½d. the dozen boxes—they can be got for 1½d.—abnormally heavy rates are a serious factor with match manufacturers located in London.

London and Provincial Wages.— Upon the question of wages in London shipbuilding yards, it may be interesting to compare them with the rates ruling elsewhere. The figures below are taken from the Tenth Abstract of Labour Statistics of the United Kingdom, 1902-1904 (Cd. 2491):—

Boiler Maker's and Iron Shipbuilders' Weekly Rate of Wages (new work).

	Platers' (heavy).		Platers' (light).		Rivetters.		Weekly Hours of Labour.
	Boiler Shops.	Ship-yards.	Boiler Shops.	Ship-yards.	Boiler Shops.	Ship-yards.	
London	45/-	45/-	42/-	45/-	38/-	38/-	54
	48 ‡	48/-	45/-	48/-	42/-	42/-	45½
Newcastle	40/6	35/-	38/6	35/-	37/6	33/-	53, 54, 48½†
Sunderland	41/-	35/-	39/-	35/-	37/6	33/-	53, 47†
Glasgow ..	41/9	36/-	38/4½	36/-	36/1½	33/9	54
Belfast ...	42/6	38/6	42/6	...	37/-	35/6	54

† In shipyards in winter. ‡ Repair work.

It will be seen that the London wages are considerably higher all round, and the figures given above do not disclose the whole difference. For night work, London men want to be paid at the rate of time and a-half. In the North, the men get time and a quarter, or time and one-eighth. Again, the rating of machinery in London is a serious matter. In some of the poor and industrial boroughs it is rated as high as 10 per cent. of its capital value, which means, with rates, as in Poplar, at 12s. in the £, that for every £1,000 worth of machinery there is an addition of £60 to the rate-toll. If this burden was uniform all over the country, it would be borne with less complaint. But it is not so. As was recently explained in the *Journal*, the general uncertainty as to what may, or may not, be done in this direction has tempted many local authorities to make assessments, whilst others make none. Thus, in Westminster, machinery is not rated, in the City of London it is partially rated; in Poplar it is heavily rated, in Manchester it is not rated at all. This lack of uniformity causes confusion and ill-feeling, and presents itself as an unfair burdening of manufacturers resident in certain localities. It is to be hoped that the Bill which has been before Parliament many years, and is intended to secure uniformity of rating in accordance with the recommendation of two Royal Commissions, will soon become law, and so put an end to an irritating anomaly.

GENERAL NOTES.

PROPOSED COMMERCIAL AGENTS FOR THE COLONIES.—Mr. C. F. Just in the paper he contributed to the Colonial Section last session on the manufactures of Canada, advocated the creation of a service of commercial agents to reside in British possessions for the purpose of reporting to the Commercial Intelligence Branch of the Board of Trade in London, "on all matters concerning the resources, growth, local enterprises, public contracts, openings for trade, and the investments for capital," as is done by His Majesty's consular officers and commercial *attachés* in regard to foreign countries. The superintendent of Commercial Agencies in Canada has expressed his firm conviction that the establishment of such a service would be of immense benefit to the Empire at large. He adds that there is not in the whole of Canada a British official who can answer questions of the British exporter concerning Canada, while the Americans "have in the neighbourhood 190 officials."

BRITISH SOLOMON ISLANDS.—At present the trade of the Protectorate is done exclusively with Sydney, and this is due to the fact that there is no steam communication with any other place. But it cannot be said that Sydney does much to help the Protectorate. Of its exports, copra

at present enters Australia free of duty, some being manufactured into oil and oil cake in Sydney, but most of it is re-exported to Europe. Under the operation of the New South Wales Harbour Rates Act copra manufactured into oil and oil cake in Sydney is subject to a wharfage charge of 10d. per ton, while copra entering Sydney for re exportation pays a wharfage charge of only 5d. per ton. The other articles of export from the Protectorate are all re-exported from Sydney to Europe with the exception of *bêche de-mer*, which goes to China. In his report on the islands just published, the Commissioner, Mr. C. M. Woodford (Cd. 2684) anticipates that Sydney will before long lose this trade. The output of copra will have so much increased that either a mill for crushing will be erected in the Protectorate, or the copra will be freighted direct to Europe in sailing vessels. And if, as is likely, the Nord Deutsche Lloyd Company, having practically closed the German New Guinea Colony and the Bismarck Archipelago to Australian steamers, extend their voyages to the British Solomon Islands Protectorate, and offer better terms of freight than those now prevailing, as they would be able to do in consequence of the heavy subsidies and concessions received from the German Government, a large proportion, at least, both of the export and import trade of the islands will be diverted from Sydney to Singapore.

CAPE TOWN PHOTOGRAPHIC SOCIETY. — A photographic exhibition will be held at the City Hall, Cape Town, from Saturday, February 3rd, to Saturday, Febuary 10th (inclusive), under the patronage of the Governor. Entries close January 13th, 1906. Section A is open to members of any photographic society in South Africa. Section B is international and open. Section C is international and open, and includes scientific and technical photography, and its application to processes of reproduction.

BRITISH SCIENCE GUILD.—The Inaugural Meeting of the British Science Guild, held at the Mansion House, has had the effect of largely increasing the list of applications for membership. Sir Norman Lockyer desires it to be known that would-be members should apply for particulars to the Honorary Secretary, 16, Pen-y-Wern-road, S.W.

MEETINGS FOR THE ENSUING WEEK.

MONDAY, Nov. 13...Mechanical Engineers, Storey's-gate, Westminster, S.W., 8 p.m. (Graduates Section.) Mr. Edward Barrs, "Boiler House Practice and Design."

Surveyors, 12, Great George-street, S.W., 8 p m. The First Ordinary General Meeting of the Session 1905-1906. Opening Address by the President, Mr. Charles Bidwell.

London Institution, Finsbury-circus, E.C., 5 p m. Prof. E. Ray Lankester, "The Origin of the Elephant."

TUESDAY, Nov. 14....Civil Engineers, 25, Great George-street, S.W., 8 p.m. Mr. John Arthur Saner, "Waterways in Great Britain."

Zoological, 3, Hanover-square, W., 8½ p.m. 1. Dr. Walter Kidd, "The Papillary Ridges in Mammals, chiefly Primates." 2. Mr. J. Lewis Bonhote, "A collection of Mammals brought home by the Tibet Frontier Commission." 3. Dr. Einar Lönnberg, "Notes on the Geographical Distribution of the Okapi." 4. Major George H. Evans, "Notes on Goral found in Burma." 5. Miss Dorothea M. A. Bate, "The Mammals of Crete."

Statistical, 9, Adelphi-terrace, W.C., 5 p.m. Sir J. Athelstane Baines, "Statistical Skimmings from the International Congress."

Colonial Inst., Whitehall Rooms, Whitehall-place, S.W., 8 p m. Mr. W. J. Sowden, "The Anglo-Australian position from an Australian point of view."

WEDNESDAY, Nov. 15...SOCIETY OF ARTS, John-street, Adelphi, W.C., 8 p.m. Sir Owen Roberts, Chairman of the Council, "Inaugural Address of the 152nd Session."

Meteorological, 25, Great George-street, S.W., 7½ p.m. 1. Sir John W. Moore, "The Rainstorm of August 24th-26, 1905, in Co. Dublin and Co. Wicklow." 2. Dr. William B. Newton, "The Aquameter."

Microscopical, 20, Hanover-square, W., 8 p.m. Exhibition of Microscope Slides of Tsetse-Fly Dissections, Trypanosomes, &c.

THURSDAY, Nov. 16 ..Linnean, Burlington-house, W., 8 p.m. 1. Miss Margaret Benson, Miss Elizabeth Sanday, and Miss Emily Berridge, "Contributions to the Embryology of the Amentiferae," Part II. 2. Prof. Chas Stewart, "The Ears of Certain Sharks."

Chemical, Burlington-house, W., 8½ p.m. 1. Mr. J. E. Reynolds, "Silicon Researches (Part IX.) Bromination of Silicophenyl Imide and Amide, and Formation of a Compound including (Si N)." 2. Messrs. J. E. Marsh and R. de J. F. Struthers, "Condensation of Ketones with Mercury Cyanide." 3. Messrs. G. Barger and A. J. Ewings, "Application of the Microscopic Method of Molecular Weight Determination to high Boiling Solvents." 4. Mr. R. G. Durrant, "Green Compounds of Cobalt produced by Oxidising Agents." 5. Mr. W. H. Perkin, Jun., "Synthesis of Tertiary Menthol and of Inactive Menthene." 6. Messrs. R. H. Pickard and A. Neville, "Optically Active Reduced Naphthoic Acids, Part I. Dextro-dihydro-1-naphthoic Acid."

London Institution, Finsbury-circus, E.C., 6 p.m. Mr. Hilaire Belloc, "The Oldest Road in India."

National Indian Association, in the Jehangir Hall, Imperial Institute-road, S.W., 4½ p.m. Mr. Theodore Morrison, M.A., "Indian Muhammadans and European Culture."

FRIDAY, Nov. 17...Art Workers' Guild, Clifford's-inn Hall, Fleet-street, E.C., 8 p.m.

Architectural Association, 18, Tufton-street Westminster, S.W., 7½ p m. Mr. J. A. Gotch, "Old Manor Houses."

Mechanical Engineers, Storey's Gate, Westminster, S.W., 8 p.m. Dr. H. C. H. Carpenter, Mr. R. A. Hadfield and Mr. Percy Longmuir. The Seventh Report to the Alloys Research Committee: "On the Properties of a Series of Iron-Nickel-Manganese-Carbon Alloys."
